THE INFLUENCE OF VITAMIN E ON VASCULAR DISEASE

EVAN V SHUTE, B.A. MB F.R.C.S.C.

ARTHUR B VOGELSANG B.A. MD FLOYD R SKELTON MD London Canada, and

WILFRID E SHUTE, B.A. MD Guelph Canada

IN 1942 Mason (2) reported that the classical fetal resorption in E-deficient pregnant rats was due to such vascular abnormalities in the uterine wall as stasis, distention and thrombosis (notably venous). Occasionally these conditions terminated in ruptures into the decidua with frank hemorrhage. In E-deficient chicks analogous phenomena are also seen, and there is some evidence in them too of functional alteration of the capillary walls.

At about the same time Shute (6) stated that senile vulvovaginitis treated with high doses of the tocopherols often was clinically improved. Biopsy of vulvar tissue after such treatment revealed an appearance suggesting either the proliferation of new capillaries or the reopening of old collapsed capillaries. But the definite lag of 2 to 4 weeks before improvement showed itself suggested the former as being the more likely. On *a priori* physiological grounds it was the more tenable explanation, too.

Mason (3) has also pointed out that in both the monkey and hamster vascular degeneration is a prominent feature in the picture of prolonged vitamin E deficiency. Shute (8) has recently reported the rapid response to intensive tocopherol therapy of 3 patients with acute hemorrhagic nephritis, indicating an ef-

fect on the glomerular capillaries. Other observations (7, 11) we have made on the purpuras indicate that the tocopherols decrease capillary permeability and increase low platelet counts. However it was the influence of the tocopherols on coronary thrombosis and other cardiac processes (1, 3, 14, 15) that recently turned our attention directly to the effect of tocopherols upon pathological conditions of the vascular system. It was noted that many arteriosclerotic cardinals given tocopherols reported that feet and hands that had been cold and numb for years had suddenly become warm again. Many had had small indolent ulcers which now healed rapidly. We could scarcely fail to investigate certain types of peripheral vascular disease in following up such clues.

CLINICAL STUDIES

What follows is an account of our experiences with tocopherol therapy in a series of patients having vascular disease.

Thrombophlebitis and phlebothrombosis
Twenty two cases of this condition have been studied. Three typical examples will be described briefly.

CASE 1. Miss M. (courtesy Dr. R. Schram) aged 50 years. This girl developed an acute left femoral thrombophlebitis May 28, 1946, the third day post partum. The area involved was about 4 inches long in the left midthigh, and there was at the same time a phlebotic mass 3 centimeters in diameter in the left

the platelets out of circulation. Clinical improvement in these patients is coincident with a rise in platelet count and an apparent resorption of the fibrin mesh. On the other hand older and organized thrombi are usually associated with higher platelet counts, do not seem to screen out platelets and do not respond to the same dosage of tocopherols. Perhaps double the usual dose is required—often as high as 600 milligrams of the alpha form. Can it be that tocopherols attack fibrin directly by a proteolytic process? A decrease of platelets and a persisting high sedimentation rate on tocopherol therapy is an indication either of recurrence or extension, and demands an increased dose.

The bearing of these observations upon our views on cerebral and coronary thrombosis is too obvious to be labored here of course.

Should all puerperal women be given tocopherols in an effort to avoid thrombosis? Such therapy might also promote lactation in a few such women (5) but of course should not be instituted until the third day at least in toxemic mothers for fear of precipitating eclamptic convulsions (9). Many herniotomies and pelvic operations might benefit similarly from prophylactic dosage.

Indolent ulcers of the leg and ankle. We have studied 13 of these and will describe 4 typical examples.

CASE 4. Mr. H. aged 63 years a railway news agent. His right leg had been ulcerated at the ankle off and on for 19 years. There was considerable generalized arteriosclerosis and a normal blood sugar. The present exacerbation dated from 1945. When first seen by us on September 16, 1946 he had been in bed for a month with the right leg literally covered from toe to knee with old and recent open ulcers of all sizes up to 2 inches in diameter. During that month he had been treated with local applications with little or no relief. He was promptly given 250 milligrams of a tocopherol per day by mouth. He began to show improvement in a few days. Time was nearly healed in 8 weeks and was completely healed in 10 weeks. He returned to work November 16, 1946 and has been well since working on the rail road again.

CASE 5. Mrs. C. aged 6 years a wife living alone. For 18 years she had had recurrent varicose ulcers of both lower legs. She came under our observation in December 13, 1946 for a funus carcinoma. It was incidentally noticed at that time that her left leg was in an Unna's boot. Both shins were

badly scarred from old ulcerations. She had had an indolent varicose ulcer over the left internal malleolus for the previous 6 months, and had worn an Unna's boot during that period of time without much benefit.

The boot was removed she was curetted and given deep roentgen therapy and kept in bed. After December 14 she was given 300 milligrams of a tocopherol per day by mouth. In 10 days time the old ulcer had greatly improved and in 17 days was well healed. The leg has remained well since. She was discharged February 2, 1947. She is now quite active doing her own housework.

CASE 6. Mrs. A. aged 82 years had suffered from varicose veins of both legs since 20 years of age. She had had varicose ulcers occasionally since 30 years of age the last one appearing in 1938. The present episode began in August 1946. When first seen by us on December 7, 1946 there was a typical varicose ulcer over the internal malleolus of the left ankle. It was 3 centimeters in diameter with a dirty sloughing base. Several tiny ulcers were to be seen over the external malleolus of the same leg. Her urine was normal. She was put to bed for 9 days and given 300 milligrams per day of a tocopherol. There was so much improvement in the ulcer in that time that she was allowed up. By the 23rd day of treatment the ulcers were greatly improved and healing was complete on the 30th day. She has been well and active since.

CASE 7. Mrs. C. aged 54 years. This woman had been troubled with varices in the left leg since 1922. At that time she had had a venous ligation done. She had had phlebitis five times since once in both legs. In 1941 an ulcer developed over the left internal malleolus and it had never healed completely since. For the past 3 years it had covered the mesial and anterior aspect of the lower leg and when she presented herself it was about 4 inches in diameter square in contour with a stinking sloughing base.

She was admitted to hospital March 8, 1947. Her blood and urine were normal. She was afebrile. Her usual local treatment was applied and penicillin was used as well both intramuscularly and locally. On March 18 one of us suggested that the penicillin be discontinued and that she be given 5 milligrams of a tocopherol per day by mouth. She had steady and rapid progress thereafter getting out of bed after March 21. By March 25 the slough had all cleared away from the surface of the ulcer, the odor had gone, fresh granulation covered the whole bed and penicillin of epithelial tissue had grown in over the granular surface for as much as a centimeter in many places. By March 30 the epithelialization had progressed considerably in some places encroaching 3 centimeters or more into the ulcerated area. She was discharged from hospital on April 12.

The ulcer was next seen on April 26 at which time it was well healed except for an area at the center 3 centimeters in diameter. This was reduced to half its size by June 3. On July 10 the ulcer was completely healed.

All the other patients did as well as those described here.

The response achieved in these patients was both prompt and lasting. It was ascribed to improvement in local arteriolar circulation and to better oxygen utilization by the local tissues. During treatment the affected extremity sometimes became warmer than its mate.

These studies may bear on the problems of plastic surgery.

Early gangrene of the extremities. We have studied 3 such cases and will describe one of them in detail.

CASE 2. Mr McK (courtesy Dr W Harbilly) aged 74 years. He was admitted to hospital in London on March 29, 1941, displaying well areas of dry gangrene on the dorsum of both feet and legs, large deep gangrenous areas 2 1/4 inches in diameter in front of and behind the left lateral malleolus and a large area of dry gangrene over the right tendo achillis. Both legs were inflamed, discolored and edematous half way to the knees. The patient said he had been "itching around in the feet" in his boots for several days before admission. His hands were a dusky cyanotic color. The blood sugar a normal but the no protein nitrogen was 43 milligrams per cent and his sedimentation rate 76 N.E.S. Studies of his legs showed considerable calcification of the posterior tibial artery, much more marked in the left leg. The left popliteal did not pulsate and the right pulsed only very faintly.

Beginning on March 21 he was given 500 milligram of a tocopherol acetate per day by mouth. On the 26th he complained of pain and needles in his feet and a change for the better was apparent at the upper limit of his lesions. His feet and legs were no longer edematous. His hands were no longer cyanotic. On the 28th a pulsation in the left popliteal artery was first palpable. By the 30th most of the edema of the legs and the dorsum of the feet had sloughed off leaving normal pink skin underneath. At this time the more superficial gangrenous areas were rapidly healing under loosening scabs. By April 6 several of these had been cast off and a pulsation could be detected in both posterior tibial arteries for the first time. By April 18 his right leg and foot were almost normal in appearance. On the left foot only a few of the deeper scabs remained. On April 23 his nonprotein nitrogen was 43, creatinine 1.1 and sedimentation rate 35. The corresponding values on May 2 were 43, 1.1 and 17. By April 25 both feet were healed and the patient began to walk about.

When he went into hospital amputation of both legs above the knee seemed to be the treatment of choice. Amputation is no longer necessary. He still takes 500 milligrams a tocopherol per day.

The first case of early gangrene of an extremity treated with tocopherols was a woman of 76 years of age who was admitted to hospital December 8, 1946, for an acute diverticulitis which was promptly operated upon. Her left leg at that time showed early but discrete and superficial gangrenous areas extending as high as the knee. She was a mild diabetic under good dietary control but with arteriosclerosis. After December 11 she was given 100 milligrams of a tocopherol per day by mouth and soon showed great improvement in the affected leg. She was discharged from hospital on December 22, 1946, and has led an active life ever since doing her own housework. She still takes 5 milligrams of a tocopherol per day as a prophylactic measure. There has been no recurrence of her lesions.

What would tocopherol therapy do for frostbite, immersion foot, and similar conditions? Others with better clinical opportunities may provide the answer.

Thrombosis, angitis, scleritis and related vascular conditions. We have thoroughly studied one verified and one doubtful case.

CASE 3. M. M. T. aged 55, single. She has never used tobacco. She began to complain of pain in her toes in 1934. The toes became dusky red at times almost purple and gangrene was feared as these conditions became progressively worse. At that time a glaucoma and other such measures in hospital over a period of 15 weeks gave temporary relief. With Buerger's exercises and careful avoidance of overexertion a threat (she has always loathed her more than cold!) she maintained an approximate normal weight until July of 1946 although frequently during these intervening 12 years the toes were ulcerated. The greatest care was required to avoid a major foot infection and to heal these small ulcers. Once in 1942 she almost developed dry gangrene of several toes of both feet and was forced to spend 7 weeks in bed. The toes have been numb for years as has also been true of the feet and lower legs. When she wanted to pick up anything from the floor she could not kneel, steadily because of the numb feet but sat down in order to do so. She often awakened in the night to see if her feet were still there. There had been considerable edema of the feet and lower legs during these years, and this was not altered appreciably by a salt free diet.

On June 12, 1946, she was given 500 milligrams of a tocopherol acetate per day—our first case of peripheral vascular disease treated with the tocopherols. On the 15th she could scarcely sleep for the

tingling in her arms and legs and in the next few days purpuric areas of all sizes appeared over the trunk and extremities accompanied by sensations of "pins and needles." She had had these purpuric manifestations at her x ray menopause 10 years before but not in the interim. In 10 days time her edema decreased considerably and her toes felt warm and had practically returned to normal color. By July 23 her feet and toes were no longer numb. She now could kneel on the floor to work or pick things up. Trauma to the toes was now felt as pain. On three or four occasions she stopped her tocopherol therapy or reduced the dose but each time her edema and other difficulties recurred promptly. Her chiropodist could always detect changes in her dosage. Her corns began to trouble her again as soon as sensation returned to her toes and they regained their usual color. Actually it seemed to her that the corns grew faster than before. She is now leading a very active life as a practical nurse on a difficult case.

We are well aware of the fact that the diagnosis in this case is questionable and that to call it Raynaud's disease might be more accurate. However the vascular relief achieved provides our reason for presenting it.

CASE 10. Mr S. K., aged 48 a veteran of the last war. In the winter of 1944 he experienced a good deal of pain in his fingers and toes. They often felt intensely cold and would assume a dead white appearance. In June 1945 he was sent into hospital for a stubborn ulcer on the ball of the left thumb. The palmar aspect of the right thumb then displayed extensive areas of dead white skin and ached. His toes also were white but not as white as the thumb. They too were cold to the touch and ached. His other fingers ached constantly too. When the ulcer on the thumb healed other ulcers appeared on the tips of other fingers some of them on the other hand. A diagnosis of Raynaud's disease was made. In October of that year the ring finger of his left hand was ulcerated at the tip. Neither detailed examination by a neurologist nor laboratory studies were helpful.

On a later hospital admission in September 1946 an x ray examination of the hands revealed osteolytic reaction involving particularly the distal end of the distal phalanx of the third right finger and the distal phalanx of the right index finger. His feet showed similar changes involving the distal phalanx of the 2nd right and 2nd left toes and both 4th toes. The right 5th toe showed some proliferations and cystic areas suggesting a response to vascular occlusion. Two weeks later gangrene of the second right toe appeared with swelling and redness of that toe and foot. Only an occasional dorsalis pedis pulsation could be felt. The right popliteal was palpable. Injection of 8 milligrams of mecharyl produced a temperature elevation of as much as 1.2 to 2 degrees only in the first right toe, 4th right toe and in 1st, 3rd, 4th and 5th left toes. In the remainder the flushing response was less than one degree. On Oc-

tober 25 1946 the right lower extremity was amputated by the Gritti-Stokes method. As the stump failed to heal, skin grafts were attempted in November 1946 and January 1947 but both failed to take.

The pathological report on the amputated leg revealed thickened vessels, showing in one place an old organized canalized thrombus. There was intimal hyperplasia, a lymphocytic infiltration of the media and a thickened adventitia. The small vessels showed either marked narrowing of the lumina or organized blood clot filling them. There was no evidence of calcification anywhere.

The condition of the other leg rapidly became worse and when first seen by us on February 13 1947 he had been sent home on 2 weeks leave before returning to consider its amputation. The site of the unhealed skin grafts was a raw ulcer. For a fortnight he was given 300 milligrams of a tocopherol acetate per day by mouth but not required to reduce his cigarette consumption. By the 4th day of treatment he began to feel improvement. On the 8th day increased urination developed and he no longer experienced pain in his extremities. By February 24 his phalanges were normally warm and of good color. The recalcitrant stump ulcer was now completely healed and felt normally warm. On March 14 he was able to walk on his artificial leg for 4 hours without discomfort and his hands and remaining foot seemed nearly normal. He bought a truck and decided to begin a trucking business. However he was unable to get tocopherol capsules for a 2 week period in April. When he next reported on May 1 he showed a recurrence of the stump ulcer. He was promptly given tocopherols again and the ulcer healed as promptly as at first. He was working as a trucker when last heard from at the end of May.

Another typical case has had a fine result. It should be mentioned that these patients often suffer a good deal as their circulation improves. During that time they may be difficult to maintain on treatment.

Our former colleague, Dr C. K. Stuart, has treated with tocopherols 4 patients displaying intermittent claudication the results being excellent in 3 of them.

Our friend, Dr George Dowd, has treated 4 such patients between the ages of 48 and 63 years. Three of the patients became asymptomatic and one was markedly improved on doses of 400 to 1100 milligrams of mixed tocopherols daily. We have had a good result in the only case we have treated ourselves.

Cerebral thrombosis. After what has been said above on the subject of thrombosis in general, little need be added here. One of the more puzzling phases of our studies has been the trivial influence the tocopherols usually

Fig. 4. Graph showing results of treatment with tocopherol only in a case of postpartal thromboembolism.

exist on hypertension *per se* but the fact that in hypertensive heart disease there may be a small initial rise of both systolic and diastolic blood pressures coincident with increased cardiac tone and relief of decompensation which is often followed by a drop a compensation occurs. The symptoms ascribable to hypertension are often relieved out of all proportion to the improvement thus achieved. This parallels the experience of Smithwick with his surgically treated hypertensives.

We have studied a score of cases of cerebral thrombosis, most of them of months or years, as 1/2 years standing. In 12 out of the 20 cases some improvement was often achieved. As would be anticipated, the patients treated most promptly did best. Generally speaking from 10 to 25 per cent of the disability has disappeared in the group as a whole. The gain was made principally within the first 3 weeks

after which improvement went on much more slowly. It is very difficult of course to prove how much of what was gained was ascribable to tocopherol therapy and how much was spontaneous. Others must settle that point whose opportunities are superior to ours. We merely discuss the topic here for its suggestive value and because it is pertinent to this whole problem. But Dowd tells us he has seen a 50 per cent improvement in a woman whose stroke occurred 6 years previous. If cerebral thrombosis occurs in end vessels, as medical texts have long contended, the theoretical interest of the type of case is further enhanced. One of our most interesting cases was that of an elderly lawyer who had experienced his accident in 1914, 2 years before he was first seen by us. His original complaint was a cerebral aneurysm of the middle cerebral artery. His condition was to be on a permanent

basis. His blurred vision dramatically improved in 3 weeks time. Before treatment he could distinguish a person standing 6 feet away but not his features. Afterward he could differentiate all his major features.

The benefit these patients experienced may have been strictly analogous to that seen in thrombosis elsewhere. Or gliosis itself may have partially responded as in Steinberg's cases of fibrositis and fascial contracture. Both Davison and Dowd suspect that some damaged nerve cells live in a twilight state, neither dead nor yet fully alive, until such a reparative stimulus as the tocopherols reach them and enable them to regain at least a portion of their former function.

If every hypertensive were given tocopherols would the incidence of apoplexy be reduced?

DISCUSSION

The number of patients studied in each of these groups is small, but the results are of such interest, developed so promptly and have such an important bearing on the great problem of heart and kidney disease in general that it was felt they should be reported now. The color photographs appended illustrate the rapidity and extent of some of the changes described.

One cannot but suspect that the surgical and medical possibilities of the field we have stumbled into will prove both fascinating and rewarding to investigators who have better opportunities than we have. Generally speaking the tocopherols should be helpful wherever improved arteriolar circulation or better oxygen utilization in tissues is desired (10).

It would seem that when tocopherols are administered thrombosed veins relax to permit a circulation over and past the thrombus, as Pereira has clearly shown can occur with sympathetic block in like cases. The analogies of our treatment to sympathectomy are of real interest.

The need for continued treatment at high dosage levels in so many cardiovascular conditions is analogous to the situation encountered in hypothyroidism or in diabetes. It suggests that one is either replenishing a rapid wastage of tocopherols in these particular pro-

ple or combatting the continued production of some noxious bodily antagonist. Our work with the purpura would perhaps suggest the latter and may even point to that agent as being the estrogens—another indication of the truth of our old thesis that vitamin E is anti-estrogenic whatever else it is.

The matter of dosage is fundamental in tocopherol therapy. About 200 to 300 milligrams of a tocopherol per day seems to be the average therapeutic level. The fact that it is a tocopherol that is required should be stressed. In cases of acute cerebral thrombosis we have used parenteral tocopherols with success. Patients so treated seem to react in one half to one third of the usual time taken when tocopherols are administered by mouth. To achieve the best results in such cases it is important to saturate the patient as early as possible in order to minimize brain cell damage adjacent to the thrombus or embolus. Inorganic iron should not be given with the tocopherols (10).

We have even been so bold as to hazard the guess—and it can only be that in the present state of our investigations—that the tocopherols may be at least as valuable in the prophylaxis of certain vascular accidents and conditions as in their therapy. In this connection it should be pointed out that many of these conditions soon recurred after healing unless tocopherol therapy was continued at a high level permanently.

For too long medical men have considered the vitamins to be mere food accessories. But surely the time is approaching when some of them at least will rank as true chemotherapeutic agents to be administered in doses comparable to those of the sulfonamides or penicillin and for indications quite as strict that Nature thought of them as being prophylactic before we thought of them for cure just as she left medicinal molds lying about for those to pick up who could see them under their feet.

SUMMARY

In such vascular diseases as indolent varicose ulcers of the legs, thrombophlebitis, early gangrene of the extremities and even thromb-

THE VISCERAL ENDOPELVIC FASCIA AND THE HYPOGASTRIC SHEATH

EDUARD UHLENHUTH, Ph. D EDWARD C. DAY, M.D., R. DALE SMITH, Ph.D., and
EDMUND B MIDDLETON, Baltimore, Maryland

EVER since John Cameron in 1908, called attention to the significance of what he called the "perivascular sheath" as a supporting mechanism of the pelvic viscera interest in the visceral endopelvic fascia has been on the increase and numerous attempts have been made to define display, and describe accurately this system of structures in the pelvic cavity So far, however, no accord has been reached in classifying and defining the component parts of the visceral endopelvic fascia. Moreover most of the existing descriptions of this structure do not lend themselves to an easy and clear cut demonstration in the student dissecting room nor do they fulfill the requirements of the practicing surgeon

Compelled by the need of presenting this subject to both medical students and post graduate students, the senior author of this article has been engaged for the last 10 years in a study of the visceral endopelvic fascia, certain phases of which will form the topic of the present contribution

It is generally agreed upon that the fasciae of the pelvic cavity can be grossly classified under two headings, the parietal and the visceral endopelvic fascia. There exists however no agreement concerning the individual fascial structures which should be considered parietal and those which should be termed visceral. In order to avoid misunderstandings, it is necessary that we define the terms to be used in this article

PARIETAL ENDOPELVIC FASCIA

Testut considered as parietal endopelvic fascia all fasciae which cover the pelvic surfaces of the muscles lining the pelvic cavity according to this author the fasciae

From the Department of Gross Anatomy University of Maryland Medical School.

These investigations were supported by grants from the Westover Research Fund of the University of Maryland.

which cover the pelvic surfaces of the internal obturator, piriformis, levator ani, and coccygeus muscles are parietal endopelvic fascia.

Cunningham (5 6) and following him Cameron (2) describe the fasciae of the muscles of the pelvic floor (levator ani and coccygeus) as parts of the visceral fascia. Under the term of parietal endopelvic fascia these anatomists include only the fasciae which cover the pelvic surfaces of the muscles of the pelvic wall proper (parietes) i. e. the internal obturator and piriformis, and peculiarly enough also the fascia of the deep transverse perineal muscle.

Again a different grouping we find in a paper by Douglas E Derry this author is of the opinion that the fasciae of the coccygeus and piriformis are entirely different from the true parietal endopelvic fascia and should be considered by themselves as individual fasciae. Only the internal obturator and levator ani fasciae are parietal

Many other views concerning this subject are encountered in the literature too numerous to be considered here

In the following account we have adopted essentially Testut's nomenclature the pelvic fasciae covering the internal obturator piriformis levator ani and coccygeus are parietal endopelvic fascia.

VISCERAL ENDOPELVIC FASCIA

Considering the complexity of the visceral endopelvic fascia and the lack of uniformity in the description of this structure, it is not to be wondered at that some authors became discouraged and relegated this entire fascial system to the position of an undifferentiated 'packing tissue'. Outstanding among the proponents of this procedure is Douglas E. Derry who demands that the term 'visceral endopelvic fascia' be dropped entirely and be replaced by the term 'subserous tissue'

SURGERY GYNECOLOGY AND OBSTETRICS

Even where the latter is condensed into perivascular sheaths and fascial capsules these structures are lacking in definition and pass gradually into the general, undifferentiated subserous tissue. We hope to show however that the visceral endopelvic fascia is disposed in the form of well defined, strong sheet like structures of definite location attachment, and function. Anybody who has read the classical work by Peham and Amreich, of the University of Vienna, entitled *Gynaekologische Operationslehre* will admit the existence and demonstrability of the visceral endopelvic fascia, as well as the need for accurate knowledge and description of this structure.

To mention only a few of the most important functions and uses of the visceral endopelvic fascia, attention may be called to four of them

1. The visceral endopelvic fascia furnishes well defined capsules for the pelvic viscera. These capsules serve as points of attachment for important supporting structures composed of visceral fascia. Moreover the capsules contain the collecting channels of the lymphatic drainage system of the pelvic viscera. Surgeons are well aware that malignant growth if it once has broken through the wall of the viscus and invaded the capsule is prone to have formed metastases. Taking into account this fact, Jewett has recently worked out a classification of malignant growth of the bladder with respect to its operability.

2. In the form of double layered perivascular sheaths, this fascia serves as a vehicle for important vascular and nervous structures. An accurate knowledge of these sheaths enables the surgeon to locate swiftly these vessels and nerves.

3. The perivascular sheaths form partitions dividing the subperitoneal part of the pelvic cavity into fascial compartments which are completely sealed off against each other.

4. The perivascular sheaths are firmly attached to the fascial capsules and to the pelvic wall thereby mooring the viscera securely to the walls of the pelvis. As they run in different planes and are situated at different levels, they form a framework within which the viscera are suspended.

For practical purposes as well as for the purpose of teaching the component parts of the visceral endopelvic fascia may be classified as follows

1. Fascial capsules varying in thickness in different regions and enclosing the pelvic viscera. Where these organs pierce the pelvic floor the capsules become continuous with the parietal endopelvic fascia. For this reason they are often described as reflections of the parietal fascia upon the walls of the pelvic viscera.

2. A horizontal band of fascia described in the anatomical nomenclature under the name of fascia endopelvina, which arises from the parietal fascia of the levator ani along a line called the white line of the fascia endopelvina.

3. The umbilical sheath. This is a distinct fascial membrane located for the most part in the abdomen where it forms a thickened triangular band, the apex of which is attached to the umbilicus, while its two lateral sides correspond to the obliterated umbilical arteries. It contains in its midline the obliterated and laterally on either side the obliterated umbilical artery. In the pelvis it becomes continuous with the capsule of the bladder and, more laterally with the superior hypogastric fascia. In the abdomen it represents a part of the visceral endogastric fascia located between peritoneum and transversalis fascia and is especially well differentiated in newborn children. Its nature and origin have been discussed and explained by two French anatomists, Cuneo and Veau.

4. The superior hemorrhoidal sheath a distinct perivascular sheath differentiated from the dorsal visceral endogastric fascia around the branches of the inferior mesenteric artery. It descends down into the pelvis behind the rectum and fuses with the pelvic hypogastric wing to be described in detail in this article.

5. The hypogastric sheath, an extensive and well defined double layered fascial membrane which arises over the anterior hypogastric artery and gives off a number of wings.

6. The rectovaginal (rectovaginal) septum although not of fascial origin, must be mentioned.

tioned here because of its intimate fascial relationships. It is a well defined membrane interposed between the rectum dorsally and the bladder and prostate gland (vagina in the female) ventrally.

7 And finally the loose areolar tissue this is present in relatively small amounts in the spaces between the viscera and fascial sheets. It is found also sandwiched in between the two fascial layers of which the perivascular sheaths are made up containing embedded in it the vessels, nerves and other structures. The present account is intended especially to call attention to and present a description of the hypogastric sheath and its components. In addition the rectogenital septum which has been described in detail in another article, and its fascial relations as well as the fascia endopelvina will be referred to.

HISTORY OF THE HYPOGASTRIC SHEATH

Since the hypogastric sheath will form the major topic of this article it is appropriate that we discuss briefly the history of our knowledge of this structure.

According to Testut Latarjet's *Traité d'anatomie humaine* this structure was first described by Jarjavet, Abernethy and Fara beuf under the name of *Gaine hypogastrique*. These authors however as well as Testut did not see anything else of this structure but a packing tissue around the anterior division of the hypogastric artery filling in a space dorsal to the peritoneum the "pelvirectal space".

Cameron (2 3) a Scottish anatomist, in 1908 was the first one who described the hypogastric sheath under the name of perivascular sheath, as a well defined structural entity and recognized its importance as a mechanism of support and fixation for the pelvic viscera. To give expression to this specific function he suggested for it the name of "fascial mesentery" of the pelvis. While his description was incomplete and did not include all the components of the hypogastric sheath, his anatomical studies must be considered as the starting point of our knowledge of this structure.

In 1930 Peham and Amreich made the hypogastric sheath the basis of their de

scription of the visceral endopelvic fascia. Aside from the fact that they did not include all the components in their description, they used an unfortunate nomenclature homologizing certain fascial elements with one another which in reality are of entirely different nature and origin. We shall have occasion to refer to their views later on in the course of our discussion.

MATERIAL

The following description of the visceral endopelvic fascia rests mainly on the dissection of the embalmed pelvis of a colored female 29 years of age and recorded as Series 479a 1946. While the dissection was in progress its individual steps were recorded by a number of illustrations. Eleven of these are reproduced in this article, numbered successively as Figures 1 to 11. Several additional illustrations taken from dissections of other cadavers and supplementary to the illustrations of the pelvis 479a 1946 are denoted by a small letter placed after the figure number (as for instance 6a).

Special features of the specimen. The pelvis was divided into two halves by a median sagittal saw cut. The left half was left intact with the peritoneum undisturbed. It served for comparison of important landmarks while the right half of the pelvis was in progress of dissection.

In Figure 1 the left half of the pelvis with the peritoneum in place is shown. In the dissecting room we rarely ever see a normal female pelvis, a very great handicap in the study of female pelvic anatomy. This woman however had no other gross pathology but that her tubes were closed on both sides. But she possessed a very unusual anomaly the ligament of Mackenrodt was completely separate from the flaccid part of the ligament latum. A wide gap existed between them only their uterine ends were connected by a narrow pontoneal fold.

On the dorsolateral wall of the pelvis there was seen in this specimen a peritoneal fold (recorded as ridge No 8) about 1 inch wide passing caudally and ventrally. Dorsally it had a sharp falciform boundary its ventral border was round. The ventral half of its

SURGERY GYNECOLOGY AND OBSTETRICS

width was seen passing forward, under the broad ligament, toward the bladder it contained, as we will see later on, the ureter and inferior vesical vessels. Its dorsal half at a point quite a distance ventral to the ischial spine, made a turn medially and became attached to the uterus. Judging from the contents of this fold it represented as far as sex is concerned, a nonspecific structure. Only the short portion from the point where part of it turned medially toward the uterus proved to be specifically female, representing the cardinal ligament of Mackenrodt.

RECTOVAGINAL SEPTUM

The pouch of Douglas extended exceptionally far caudal in this specimen. The bottom of the pouch was only 30 millimeters (a little more than 1 inch) cranial to the floor of the pelvis. Nevertheless, as Figure 1 shows a distinct rectovaginal septum was present. It is of interest to notice that the septum was attached to the dorsal wall of the vagina from the rectum it was separated by a quantity of loose connective tissue. When the uterus and with it the vagina were pulled forward the septum followed the vagina. This condition corresponds to the situation as it exists in the male there the septum is always introduced into the prostate gland. If a finger is through a transverse perineal incision, the operator may feel reasonably certain, that the rectovaginal septum will be in front of his finger separating the finger from the vagina while dorsally the finger will be in direct contact with the rectum.

In Figure 2 a dissection is illustrated which was made to display some of the relations of the rectovaginal septum in greater detail. Cranially the rectovaginal septum is attached to the peritoneum of the pouch of Douglas its caudal end could be followed all the way down to the pelvic floor. While in many adult specimens the line of fusion is marked at the bottom of the pouch by a white line and some strong peritoneal cords bridging over this white line (as will be described in detail in another article) the inner surface of the peritoneum of the rectovaginal pouch was entirely smooth in this specimen. The

cranial end of the septum had remained separated into two limbs representing its original two layers each limb was continuous with the peritoneum of the corresponding wall of the pouch and the line of fusion, instead of being bridged over by separate cord like binders, had been grown over by a continuous layer of peritoneum.

Special pains were taken to check the statement made by Curtis, Anson and Beaton in a recent article (7) according to which the tissue separating the vagina from the rectum is composed of the fascial capsules of these two viscera and some loose cellular tissue intervening between them. It was found that the rectovaginal septum is a structure additional to and well differentiated from, the capsules of both the rectum and the vagina.

Another important relationship is shown in Figure 2. The capsule of the genital viscus is attached by its cranial end to the peritoneum beyond this point over the body and fundus of the uterus, a fascial capsule could not be demonstrated as a structure independent of the peritoneum. This condition is the rule and is well known. Exactly the same relationship holds true for the ventral portion of the fascial capsule of the rectum, as is shown in this dissection. We have found however subjects in which the ventral rectal capsule extended all the way up to the colon.

HYPOGASTRIC SHEATH AND MAIN ANCHORAGE OF PELVIC VISCERA

In Figure 3 the right pelvis is shown after most of the peritoneum had been removed. The bladder was pulled medially permitting a view into the space of Retzius both its ventral and lateral compartments can be seen. The two structures, representing the main anchorage of the pelvic viscera, are displayed. They are (1) the root of the hypogastric sheath (2) the fascia endopelvina. The fascia endopelvina forms the floor of the space of Retzius the root of the hypogastric sheath seals off the space of Retzius dorsally. The fascia endopelvina occupies a nearly horizontal plane while the root of the hypogastric sheath lies in a nearly vertical and almost frontal plane if a hand is introduced into the space of Retzius and pushed

dorsally along the lateral surface of the bladder, it slides at first along the fascia endopelvina, as far back as the ischial spine. At that point its further dorsal progress is blocked by the root of the hypogastric sheath. Further movement is then possible only in a direction cranially and ventrally along the hypogastric root, which is directly continuous with the fascia endopelvina, but forms with it an angle of approximately 90 degrees. From this account it will be seen that the main line of attachment of the pelvic viscera imitates in direction the shape of the pelvic viscera themselves, most caudally their direction is nearly horizontal after making a bend of nearly 90 degrees, they are running in a vertical direction.

Peham and Amreich recognized this correlation between the direction of the pelvic viscera and the direction of their main anchorage line. They call the fascia endopelvina the 'horizontal groundplate' the hypogastric root the 'frontal groundplate'. This nomenclature, however fails to consider that these two elements are of entirely different nature. The hypogastric root and its derivatives are essentially perivascular sheaths. The fascia endopelvina is of the nature of a true ligament, partly aponeurotic in texture and is in addition a secondary formation characteristic of man but missing in lower forms.

Figure 3 permits a gross orientation of the components of the hypogastric sheath. The hypogastric root (fascia hypogastrica dorsalis) is attached to the wall of the pelvis along a line corresponding approximately to the dorsal border of the superior ischial ramus and ends caudally at the spine of the ischium which can be palpated by a finger thrust into the lateral compartment of the space of Retzius. It arises from the parietal endopelvic fascia over the anterior division of the hypogastric vessels and over the ureter (Fig. 3). Like all its derivatives it is composed of two fairly stout membranous layers between which the ureter the vascular and nervous structures are sandwiched in embedded in some loose areolar tissue. In Figure 3 only the lateral layer of the hypogastric root is visible the medial layer will soon be demonstrated.

The hypogastric root passes forward, toward the bladder and is divided by this organ into two wings a superior hypogastric wing (fascia hypogastrica superior) and an inferior wing (fascia hypogastrica inferior). Dorsally and medially it gives off an extensive double layered membrane the presacral hypogastric wing (fascia hypogastrica presacralis).

THE HYPOGASTRIC WINGS

With the aid of Figure 3 we will now discuss the hypogastric wings slightly more in detail.

a Presacral wing. The presacral wing extends from its origin all the way across the pelvic cavity in front of the sacrum and in front of the parietal fascia covering the piriformis and coccygeus muscles meeting in the median line its fellow from the opposite side. The superior hemorrhoidal vessels enclosed in a special sheath, the superior hemorrhoidal sheath, are incorporated into the presacral wing. Where it hits the rectum it splits into its dorsal and ventral layers, embracing the rectum and furnishing for it its fascial capsule.

Cranially the presacral wing is very wide. Further caudally as it follows the curvature of the rectum it narrows down and passes forward together with the rectum, forming a fascial wing of the rectum which attaches itself laterally to the fascia endopelvina.

Between the presacral wing and the parietal fascia a space is formed, the retrorectal space. Laterally this space is sealed off against the lateral compartment of the space of Retzius by the hypogastric root. Lowley and Kirwin (p. 947 vol. 2, 2d ed.) state that the space of Retzius extends as far back as the rectum. We feel it of importance to emphasize that a hand carried back in the lateral compartment of the space of Retzius is stopped on its way to the rectum by the root of the hypogastric sheath which forms the dorsal wall of the space of Retzius and represents a partition between the space of Retzius and the retrorectal space. We will see presently how communication between these two fascial compartments can be created.

b Superior hypogastric wing. As seen in Figure 3 the superior hypogastric wing follows the lateral margin of the superior surface of

SURGERY GYNECOLOGY AND OBSTETRICS

the bladder. There it splits open into its two layers one of which becomes continuous with the fascial capsule on the superior the other with the fascial capsule on the inferolateral surface of the bladder. Ventrally it is continuous with the umbilical sheath and that part of visceral endogastric fascia which lies between the peritoneum and the transversalis fascia. Laterally it sweeps across the lateral compartment of the space of Retzius, forming the roof of this fascial space and passing up on the lateral pelvic wall, to be come continuous with the visceral endogastric fascia in the iliac fossa. In order to be able to pull the bladder medially we had to cut through the superior wing its medial (pelvic flap) contains the umbilical artery and, as we will see later on in a medial view (Fig. 6) the superior vesical branches of this artery. The lateral flap of the superior hypogastric wing passes over the hump of the pelvis, forms a fascial sheath around the iliac vessels and is continued into the iliac portion of the visceral endogastric fascia (Fig. 3).

Peham and Amreich describe (p. 197) this superior hypogastric wing under the general heading of *Das lockere Bindegewebe am plying for it the name of Lamina ligamenti umbilicalis*. In this interpretation of the lateral wing they follow evidently those who consider the entire visceral fascia of the abdominal cavity as an undifferentiated layer of extraperitoneal fat, subserous cellular tissue etc. We possess a dissection which we made in 1941 and in which the capsule of the bladder has been dissected as a continuous sheet all around the organ with the two superior hypogastric wings attached and their fascia preserved. In this specimen these wings have been demonstrated as stout, well resist considerable pull an observation which holds true for the entire hypogastric sheath. Upon studying this fascia one understands why some of the older anatomists, such as for instance Hesselbach, clung to the description of the peritoneum as a duplicate composed of an internal and an external peritoneum, even after Ruyach and, later on, Douglas, in whose book the history of this

subject may be found discussed, had separated the outer layer under the name of *membrana cellulosa* (Ruyach) or *"membrana vesiculosa"* (Douglas) from the true peritoneum.

c. *The inferior hypogastric wing*. The inferior hypogastric wing is of special importance. It represents one of the major mechanisms of fixation of the bladder and contains the ureter and the inferior vesical vessels. In cystectomy this wing must be cut through in its entire length. The urologists are therefore especially mindful of this wing it is the same structure which Hugh Jewett calls the inferolateral ligament of the bladder.

In Figure 3 we see its lateral surface (its medial side will be shown later on). It comes down from the root of the hypogastric sheath medially it is attached to the dorsolateral margin of the bladder laterally to the fascia endopelvina.

Shining through the lateral layer of this wing we always see the plexus of Santorini and several stout venous drainage channels of the plexus the inferior vesical veins. It has already been mentioned that the most caudal narrow portion of the presacral wing is attached laterally to the fascia endopelvina. And now we have learned that the inferior hypogastric wing is likewise attached to the fascia endopelvina. Presently we will see that two other leaf-like structures the fascial wing of the vagina and the rectovaginal septum, are attached to the medial edge of the fascia endopelvina.

THE FASCIA ENDOPELVINA

As mentioned the fascia endopelvina is the structure which forms the horizontal floor of the space of Retzius. Under standard conditions it arises from the levator ani fascia along the whiteline of the fascia endopelvina, a line which passes from a point lateral to the inferodorsal end of the symphysis pubis to the ischial spine. The manner of origin and condition of its special differentiations is subject to very great variations which to discuss is not the object of this article. Suffice it to say that the line seen in this specimen is (Fig. 3) not the white line of the fascia endopelvina, but the arcus tendineus of the levator ani

a second line which ordinarily runs cranial to the white line of the fascia endopelvina. In this case this fascia had no special white line it came off the levator ani fascia a little caudal to the arcus tendineus.

The most ventral part of this fascia was in this subject, differentiated into three stout ligaments or expressed more correctly it formed a fascial investment for these three ligaments. Most medially the fascia had been cut away to expose the medial pubovesical ligament and the lateral pubovesical ligament. The former we have found so far in every subject examined, female as well as male it contained wherever we looked for them reddish muscle fiber bundles which radiate out into the superficial layer of the detrusor vesicae intermingling with its fiber bundles. The lateral pubovesical ligament is found more rarely.

Further dorsal the fascia endopelvina appears as a tough band which is of white color and ends dorsally into a sharp crescentic margin the lateral true ligament of the bladder. This term is rather incorrect, since in reality this ligament is connected to the bladder only by the intermedation of the inferior hypogastric wing and since it serves also and in exactly the same manner for the attachment of vagina and rectum. However it seems unnecessary to change this generally employed nomenclature. This ligament is considerably variable we have found specimens where several crescentic margins were interposed in its course. It can be very short or as in the present case, very long it measured in this subject fully 59 centimeters (over 2 inches).

Dorsal to the crescentic margin of the ligament the fascia endopelvina comes off at a lower level and cannot be seen in this illustration. It was necessary to tilt the upper end of the pelvis forward to expose the fascia endopelvina to full view such a view is illustrated in Figure 4.

THE PORTIO CARDINALIS OF THE LEVATOR ANI

After the fascia endopelvina has been incised, the aponeurotic fibers of the lateral true ligament of the bladder were exposed

The structure which interests us however is the one located dorsal to this ligament. Underneath the visceral fascia the fleshy bundles of the iliooccygeus exactly as in the male are seen as they pass, in steep course, caudally and medially covered in this situation by a rather thin parietal fascia. But immediately dorsal to the lateral true ligament of the bladder some special levator ani fibers, mixed with aponeurotic fibers leave the major portion of the muscle and pass into the inferior hypogastric wing (Fig 4). Because of their functional significance for the cardinal ligament, we have called these fibers the portio cardinalis of the levator ani. In our specimen, this portion was approximately three-quarters of an inch long. We want to emphasize the location of these fibers they correspond in location not to the ischial spine, but are situated about an inch and a quarter ventral to the spine.

In Figure 5 a window was cut out of the inferior hypogastric wing to expose its contents. Also the superior wing was cut away from the bladder through the gap created thus, the cervix is exposed to view. The ureter and the inferior vesical vessels are seen running forward to the bladder. But just opposite the place where the special levator ani fibers are located, the uterine vessels make a sharp turn medially to enter the ligamentum cardinale. We will come back to this relation between the root of the cardinal ligament and the cardinal portion of the levator ani when we will inspect the inferior wing from its medial side.

APPROACH TO THE RECTUM FROM THE SPACE OF RETZIUS

At the caudal end of the root of the hypogastric sheath there is located an arch like toughening of the fascia (Fig 5) in exploring the lateral compartment of the space of Retzius this arch can easily be felt with the fingers. Frequently in the embalmed cadaver a hard cord like structure may be felt through the fascial covering of the arch, the nature of which will be mentioned later. Laterally this arch is attached to the ischial spine which can also be palpated with the fingers. From this origin this arch passes forward and me

SURGERY CYNECOLOGY AND OBSTETRICS

dially to be continued into the inferior wing of the hypogastric sheath, as illustrated in Figure 5. In our specimen another arch-like structure pointing dorsally with its cavity was present it marked the dorsal end of the fascia endopelvina. The space between these two arches was bridged over by fascia (Fig. 5) which indicates the transition of the hypogastric root into the fascia endopelvina. In many instances this fascial bridge is formed by fascia which is so thin that a finger may be thrust through it in other cadavers it is merely composed of some loose orange-colored fat.

We made an incision through this fascia and introduced a piece of rubber tubing through the hole created thus. Pushing the rubber tubing dorsally we observed that it appeared in the retrorectal space, between the presacral wing and the parietal fascia. In this subject the rectum was situated very asymmetrically its largest part lying to the left of the median plane. In most subjects the rubber tubing would have come out dorsal to the rectum. A second piece of rubber tubing was introduced through the incision in the fascia endopelvina, just dorsal to the cardinal portion of the levator ani without any resistance it could be pushed into the retrorectal space. As this illustration shows an incision through the floor of the lateral compartment of the space of Retzius, extending from the dorsal end of the cardinal portion of the levator ani to the ischial spine will create a hole large enough to introduce a finger. The finger can be pushed past the line of attachment of the inferior hypogastric wing to the fascia endopelvina into the retrorectal space and the dorsal circumference of the rectal wall can be palpated.

As mentioned previously the space of Retzius is sealed off against the retrorectal space, by the hypogastric root we have now demonstrated that it is partitioned off against the retrorectal space also by the floor of the space of Retzius. We have demonstrated furthermore, how we can create access from the space of Retzius to the dorsal side of the rectum. This approach to the rectum can be created without the necessity of opening the peritoneal sac.

THE INFERIOR VESICAL ARCH

In order to analyze further the inferior vesical arch a window was cut through the lateral fascial layer of the hypogastric root, through it we see the main inferior vesical vein as it passes from the bladder through the inferior hypogastric wing and inferior vesical arch into the hypogastric root.

So far we have found this arch in every subject in which we looked for it. It is by no means a specifically female feature but occurs alike in both sexes. Invariably we found a large inferior vesical venous channel passing immediately through this arch and frequently also an inferior vesical artery in Figure 5 this artery is exposed in the window of the inferior wing it could be traced through the fascia from the arch into the inferior wing as illustrated in Figure 5.

We believe that great emphasis should be placed upon this inferior vesical arch. Be cause of the readiness with which it can be palpated without opening the peritoneal sac, it serves as an important and easy to locate landmark just caudal to it the floor of the lateral compartment of the space of Retzius can be incised without injury to vessels or any other important structures, and access can be gained to the rectum.

And furthermore the inferior vesical arch is closely related to an anatomical mechanism which has the function of mooring the bladder to the pelvic wall. The arch is located just cranial to the place where the upper margin of the coccygeus muscle runs transversely across the space between the ischial spine laterally and the sacrum medially.

In our specimen this margin was apocoeu rotic and of the nature of a sharp falcliform edge. It was the cause of the existence of the arch at the dorsal end of the fascia endopelvina (Fig. 5). Behind this upper edge of the coccygeus muscle the terminal branches of the ventral division of the hypogastric vessels the inferior gluteal and internal pudendal vessels, are passing through the infra-punform space from the pelvic cavity into the gluteal region. Owing to this anatomical arrangement the hypogastric vessels where they give origin to their visceral branches are held firmly against the punformis muscle by

Fig. 1. Left half of pelvis of colored female (479 cm, 1946) 29 years of age. Peritoneum left in place.

the upper arched margin of the coccygeus muscle and are thus supplying an effective mechanism of counteracting any force which pulls on them in a ventral direction. The bladder has a tendency of being displaced forward and downward by the intermediation of the inferior hypogastric wing which arises just at the point of the inferior vesical arch and contains the inferior vesical vessels which in many cases are joined to the hypogastric vessels just cranial to the inferior vesical arch the bladder is securely moored to the pelvic wall.

It appears then that the inferior vesical arch is specifically associated with the bladder

and that the ischial spine marks the place of a specific mechanism for the anchorage of the bladder both in the female and in the male.

THE CARDINAL LIGAMENT (OF MACKENRODT)

Peham and Amreich consider the ischial spine as the place of origin of the cardinal ligament and the anatomical arrangement of the vessels which we have just discussed and which we consider specifically related to the fixation of the bladder is in the opinion of these authors a specifically female feature a mechanism of anchoring the uterus to the pelvic wall. A study of the male pelvis where

SURGERY (GYNECOLOGY AND OBSTETRICS)

FIG. 2. Part of left half of pelvis shown in Figure 1, part of rectovaginal septum and its relationship to fascial capsule of rectum and vagina. Peritoneum left in place.

FIG. 3. Right half of pelvis of female 470 mm, 946 mm. Peritoneum largely stripped away. Superior hypogastric wing cut away from its lateral attachment. Bladder pulled medially and forward. Lateral compartment of space of visible.

exactly the same arrangement exists, as well as a consideration of the direction in which the uterus pulls, would make it difficult to follow Peham and Amreich in their interpretation. The pull which the uterus exerts upon the pelvic wall via the cardinal ligament is not directed forward but medially and downward.

In order to clarify this problem we must now turn to a study of the cardinal ligament which in this specimen as we have seen was completely separated from the broad ligament and could therefore be studied individually. For this purpose we will inspect a medial dissection of the same half of the pelvis, which we have studied so far from the lateral side. This dissection is illustrated in Figure 6.

The peritoneum had been largely removed. The superior surface of the bladder with its fascial capsule intact is seen. The superior hypogastric wing cut through along the pelvic brim is now viewed from its medial and cranial aspect. The umbilical artery and one of its superior vesical branches are shining through the fascial layer. At the apex of the bladder the transition of the superior hypogastric wing into the umbilical sheath and the continuity of both of these fascial structures with the fascial capsule of the bladder are

visible. The uterus and ovary have been reflected medially. The round ligament was running across the medial surface of the superior hypogastric wing. It was separated from it to permit the medial reflection of the body of the uterus. Also the suspensory ligament of the ovary with the ovarian vessels was running across the medial surface of the superior hypogastric wing. It had to be cut through in order that the ovary might be reflected medially. In the male the vas deferens takes a course similar to that of the round ligament of the female. When seen in the pelvis, after the peritoneum has been stripped off, the vas deferens appears to take an almost horizontal course from a point where it crosses the brim of the pelvis toward the ischial spine. As shown in Figure 6a, it is situated in this course upon the medial and superior surface of the superior hypogastric wing. In this illustration made for us by Professor Carl D. Clarke from the dissection of a white male by a narrow fascial mesentery upon which it can be freely moved against the superior

Fig. 4. Same dissection as in Figure 3, but promontory tilted slightly forward to permit full view upon floor and dorsal wall of lateral compartment of space of Retzius. Superior hypogastric wing cut away from lateral margin of bladder. Fascia endopelvina incised as far dorsally as ischial spine and arch of fascia endopelvina, to expose lateral true ligament of bladder and the portio cardinalis of levator ani.

hypogastric wing. This relationship is of importance. It means in the first place that the vas deferens descends nowhere to the level of the pelvic floor and secondly that it is strictly separated by the two fascial layers of the superior hypogastric wing and the structures enclosed between them from the space of the lateral compartment of the space of Retzius. In a similar manner the round ligament and the ovarian vessels of the female are separated from this space by the superior hypogastric wing.

By thrusting the hand into the lateral compartment of the space of Retzius and against the lateral side of the hypogastric root it was ascertained that the ridge No. 8 which we saw in Figure 1 was only the medial side of

Fig. 5. Same dissection as in Figures 3 and 4, windows have now been cut into the lateral layer of the inferior vesical arch and inferior hypogastric wing. Through the former the inferior vesical vein is visible. In the latter the uterine vessels are exposed to view. Also it is seen that the vesical structures pass forward toward the bladder whereas the uterine vessels make an abrupt medial turn toward the uterus. The place where the uterine vessels turn medially represents the lateral root of Mackenrodt's ligament and lies at the same transverse level as the portio cardinalis of the levator ani. Body and fundus of uterus have been cut away. The fascia closing the space between the inferior vesical arch and the arch of the fascia endopelvina was incised and a piece of rubber tubing (x) was pushed through the incision. A similar piece of rubber tubing (y) was pushed through the floor of the lateral compartment of the space of Retzius, just dorsal to the portio cardinalis. Both tubes appeared in the retrorectal space, dorsal to the presacral wing and the rectum.

the root of the hypogastric sheath. The medial fascial layer of the hypogastric root was now carefully removed and cut away. Its cut edges are visible and the lateral layer which was seen upon inspection of the space of Retzius, is now seen from the medial side in the spaces between the vessels.

The contents of the hypogastric root are clearly seen. They consist of the anterior di-

SURGERY GYNECOLOGY AND OBSTETRICS

Fig. 6 Same pelvis as shown in Figures 3 to 5, but showing dissection of on medial aspect. Both the suspensory ligament of the ovary and the broad ligament have been cut in order to permit medial reflection of uterus and ovary. The genital stump of the suspensory ligament is seen attached to the ovary. The genital stump of broad ligament was left with the uterus. The superior hypogastric root and one of its superior vesical branches in the medial layer of fascia of the hypogastric wing is now seen from the hypogastric wing has been removed. In the former the ureter and the hypogastric vessels with their visceral branches are seen passing caudally. In the latter the ureter and vesical vessels are passing forward. The uterine vessels are seen turning medially to enter the Mackenrodt's portion of the broad ligament. The falciform portion of this ligament is seen as it connects the ovary with the uterus. It contains the anastomosis between uterine and ovarian vessels.

visions of the hypogastric vessels, of the visceral branches of these vessels, and of the ureter. The uterine and inferior vesical arteries arise separately. The rectouterine muscle corresponding to the sharp dorsal margin of ridge No. 8 in Figure 1 is seen as it had been dissected out of the fascia. All these structures pass nearly vertically from cranial to caudal. At a point corresponding to the place where upon inspection of the space of Retzius, we had seen the inferior vesical arch the vascular structures begin to take a forward course entering the inferior hypogastric wing the medial layer of which has been removed in

order to expose its contents. In this wing all the vesical branches and the ureter pass forward toward the bladder. Exactly the same situation is found in the male pelvis. Therefore no good reason to include anyone of these parts under the name of Mackenrodt's ligament. In particular it seems incorrect to count the entire hypogastric root as Curtis, Anson and Beaton (?) did as part of Mackenrodt's ligament, or to count the part of the inferior hypogastric wing immediately ventral to the ischial spine, as part of Macken-

Fig 6a. Right half of pelvis of a white male (479-1945) aged 69 years. Peritoneum removed everywhere except for the rectovesical pouch and septum. The hypogastric sheath is seen in its entire extent. The vas deferens passes across the superomedial surface of the superior hypogastric wing and is thus excluded from the space of Retzius.

rod's ligament, as Peham and Amreich did. The beginning or root of Mackenrodt's ligament as a specifically female element, is clearly marked. It lies at the point where the uterine vessels are making a sharp medial turn branching away from the inferior hypogastric wing nearly at a right angle. Its distance ventral from the inferior vesical arch and ischial spine measured in the sagittal plane was 33 millimeters (more than 1 inch).

It becomes immediately obvious that the ischial spine and the relations existing there between the vessels and the coccygeus muscle as discussed previously, can serve only remotely by the intermediation of the inferior hypogastric wing as a means of uterine fixation.

In looking for structures which are specifically developed to counteract the medial pull of the cardinal ligament, we recollect now the portio cardinalis of the levator ani (Fig. 4) a series of fleshy and aponeurotic bundles inserted into the inferior hypogastric wing at exactly the place where the uterine vessels are branching off into the cardinal

Fig 6b. Right half of pelvis of a white male of unknown age (479a, 1945). Peritoneum removed (except for the peritoneum of rectovesical pouch and septum) and elements of hypogastric sheath exposed to view. The vas deferens is seen running across superomedial surface of superior hypogastric wing, attached to it by a "fascial mesentery".

ligament. We observed that pulling on the cardinal ligament in a medial direction puts these fibers on tension. It is obvious that the specific function of the cardinal portion of the levator ani is that of fixing the root of the cardinal ligament to the pelvic floor. This interpretation agrees well with the fact that in the male the cardinal portion of the levator ani is absent.

In this connection it is interesting to speculate on the effects which the peculiar anatomical relation existing between ureter and uterine vessels at the point where these vessels turn medially may have upon the ureter. Throughout the largest part of their course the uterine vessels are running dorsal to the ureter. At the point where these vessels turn medially they pass first to the lateral side of the ureter and then hook around its ventral aspect. It is evident that by this arrangement the ureter being encased firmly between the two layers of the inferior hypogastric wing

Fig. 7. Next step in the dissection shown in Figure 6. Rectovaginal septum dissected way from rectum. Septum and ectovaginal pouch (of Douglas) pulled forward to permit a lens into the preperineal space. Also the lateral peritoneal wing of the pouch and its attachments are visible.

Fig. 8. Same dissection as in Figure 7 but rectovaginal septum has been dissected way from il of vagina. Septum and ectovaginal pouch pulled dorsally to permit a view into retrovaginal space. Also the ventral surface of the lateral fascial wing of the pouch and the dorsal surface of the lateral fascial wing of the vagina are visible. A ureteral catheter was introduced into an incision made in the lateral partment of the space of Retzius.

is made a counterpoise against the medial and downward drag exerted by the uterus upon the cardinal ligament thereby aiding in some measure the other structures which serve as these anatomical and mechanical relation ships it would appear probable that in the female certain conditions may arise where the uterine vessels are enabled to cause a strangu tor and muscle and the structures of the levator diaphragm surrounding the introitus, both of which are important components of the entire supporting system of the uterus, should fall owing to damages received for e during childbirth and the cardinal ligament alone is no longer able to prevent a dal dislocation of the uterus, it is conceiv e that the drag of the uterine artery may come so great as to produce a strangulation of the ureters which owing to their fixation within the inferior hypogastric wing would be unable to give way and thus relieve the pres-

sure exerted upon them by the uterine vessels. Ever since Tandler and Halban in 1907 (quoted by Bretttauer and Rubin) published their studies on prolapse of the uterus, it is known that hydroureter is a condition which is conspicuously often associated with pro lapse of the uterus. These findings were con firmed later on (In 1923) by Bretttauer and Rubin moreover these authors suggested actually that the cause of the frequent as sociation between these two disorders is the strangulation of the uterus by the drag of the uterine vessels. Unfortunately nobody seems to have furnished actual evidence in favor of this theory by dissection of suitable cases. Everett in his book on female urology quotes Bretttauer and Rubin but does not adduce any literature actually confirming the suggestion made by these authors. Should this theory however prove correct, it would furnish addi-

Fig. 9. Caudal portion of dissection shown in Figure 8 to show a further stage in this dissection. Capsule of vagina and its lateral expansion have been dissected away from the bladder and inferior hypogastric wing respectively. The inferior hypogastric wing with the ureter in it, is seen from a dorsomedial aspect, the lateral fascial wing of the bladder capsule presents its ventrolateral surface. The ventro vaginal space is exposed to view.

tional evidence to show that the ureter wing to its firm encasement between the two fascial leaves of the inferior hypogastric wing, and its peculiar anatomical relationship with the uterine vessels, does not easily yield and is capable of aiding under normal conditions of stress in mooring the uterus to the inferior hypogastric wing. Incidentally it would seem that in case of correctness of these assumptions, the strangulation of the ureter could be abolished by ligating and severing the uterine artery and relying on the ovarian artery for the blood supply of the uterus especially so as this latter artery plays the major rôle in the blood supply of the uterus after the first pregnancy.

On the basis of the evidence here presented we come to the conclusion that the lateral root of the cardinal ligament does not lie opposite the ischial spine but is located more than 1 inch ventral to the spine that in the female alone a structure the cardinal portion of the levator ani is developed and that the specific function of this structure is to moor the root of the Mackenrodt ligament to the pelvic floor and thereby give support to the uterus.

ATTACHMENTS OF RECTOVAGINAL SEPTUM

Since the rectovaginal septum and its attachments are the cause of a subdivision of the

Fig. 10a. Right half of pelvis of white male (47941, 1945) of 60 years of age. Peritoneum removed to expose elements of hypogastric sheath. Hypogastric root has been dissected away. Superior hypogastric wing was cut away. Bladder was cut away from inferior hypogastric wing and pulled out of the pelvis. Rectum pulled medially. The lateral margins of the inferior hypogastric wing, the rectovaginal septum and the lateral fascial expansion of the rectal capsule are seen attached to the medial margin of the fascia endopelvina like the leaves of a book.

subperitoneal space of the pelvic cavity into a rectal and a genitourinary compartment it is appropriate that this subject be discussed here somewhat more in detail. The dissections which elucidate this point are illustrated in Figures 7 and 8.

With the aid of the fingers and a blunt instrument the rectovaginal septum was first separated from the rectum (Fig. 7) and then from the dorsal wall of the vagina (Fig. 8). In both instances it could be followed laterally beyond the lateral boundaries of the rectum and vagina to the medial margin of the fascia endopelvina, to which it was attached. At the same time a lateral wing of fascia arising from the capsule of the rectum and representing the caudal continuation of the presacral wing of the hypogastric sheath and a similar wing arising from the lateral margin of the vagina could be demonstrated the former is seen from its ventral aspect in Figure 7 as it extends laterally from the rectum the latter is

Fig. 9. Continuation of the dissection shown in Figure 8. The presacral hypogastric wing has been raised from the presacral fascia. It is seen as it covers the coccygeal muscle and has been reflected forward to permit view into the retrorectal space. This space is seen the autonomic nerves as they pass forward and laterally to enter the pelvic ganglion. The latter has not yet been dissected out. The sympathetic branches arise from the sympathetic ganglia, the other branches arise from the sympathetic plexuses of the sacral nerves. In the retrorectal space are seen also the rubber tubes which were pushed through the floor of the space of Retzius to show the relationship between this latter space and the retrorectal space.

seen from its dorsal aspect in Figure 8 as it rises to its fusion with the cardinal ligament. Both the rectal and the vaginal wing extended laterally toward the fascia endopelvis gain this attachment along the medial margin of the latter cranial and ventral to the line of attachment of the rectovaginal septum. In Figure 9 the ventrocranial surface of the vaginal wing is seen as it was displayed by dissecting it away from the inferior hypogastric wing which is illustrated with its medial leaf incised and reflected to show the structures that are contained in it (only the ureter has been illustrated).

From the description presented here it follows that the medial margin of the fascia endopelvis represents a line along which in the female four leaf like structures are attached from ventrocranial to dorsocaudal these are: (1) the inferior hypogastric wing of the bladder (2) the lateral fascial wing of the vaginal rectovaginal septum and (4) the lateral fascial wing (caudal continuation of presacral hypogastric wing) of the rectum. Upon this line of attachment the four leaf like structures can be turned like the leaves of a book. Grasping any one of the three pelvic viscera, after the dissection illustrated in Figures 7 & 9 had been finished, it could be freely moved back and forth upon its fascial wing. In the male pelvis owing to the absence of the vagina there are present only three of these leaves. They are illustrated in Figure 9a dorsally from the symphyseal pubis to the spine hypogastric wing the rectovesical septum and the ventral layer of the lateral fascial wing of the rectum.

Returning now to the rectovaginal septum it is seen in Figure 7 that it extended in this case as it did in many other subjects, far up cranially along the lateral margin of the rectovaginal pouch (in Figs. 7 and 8) forming a lateral wing by means of which the pouch gained a firm attachment to the presacral hypogastric wing lateral to the rectum and close to the origin of the presacral wing from the hypogastric root.

From this description it is obvious that owing to the presence of the rectovaginal septum and the nature of its attachments, the subperitoneal space of the pelvic cavity is divided into two strictly separated compartments a dorsal or rectal compartment and a ventral or vesicovaginal compartment. Similarly in the male, the rectovesical septum divides the subperitoneal portion of the cavity of the pelvis minor into a rectal and vesicoprostatic compartment.

THE FIVE FASCIAL SPACES OF THE PELVIC CAVITY
Altogether the subperitoneal space of the cavity of the female pelvis minor is subdivided

into five fascial spaces by four partitions three of these are represented by the three major pelvic viscera, their fascial capsules and the lateral fascial extensions of these capsules while one the rectovaginal septum is a fasciopentoneal sheet. In the male pelvis there are only four such fascial compartments

These fascial spaces are illustrated in Figures 3 7 8 9 and 10. They are from ventrocranial to dorsocaudal (1) the space of Retzius (lateral and ventral compartments) illustrated in Figure 3 (2) vesicovaginal space (Fig. 9) (3) retrovaginal space, between the vagina and the rectovaginal septum (Fig. 8) (4) prerectal space, between rectovaginal septum and rectum (Fig. 7) and (5) retrorectal space (Fig. 10) between the rectum and presacral hypogastric wing ventrally and parietal fascia dorsally

THE LATERAL COMPARTMENT OF THE SPACE OF RETZIUS

Of these five fascial compartments the space of Retzius is the most spacious and extensive one. Because of its easy extraperitoneal access by the suprapubic route and because of its important relationships the lateral compartment of the space of Retzius merits a special discussion of its boundaries and communications.

The lateral compartment of the space of Retzius may be said to have two side walls (a lateral and a medial wall) a floor and a roof and a dorsal wall. Ventrally it is in open communication with its partner of the opposite side via the ventral compartment of the space of Retzius. Dorsally it extends as far as the ischial spine.

Its lateral wall consists of the parietal endopelvic fasciae covering the pelvic surfaces of the internal obturator and of that portion of the levator ani which lies cranial to the white line (origin) of the fascia endopelvina. In this wall are located the entrance into the obturator canal the obturator vessels, and the obturator nerve.

The medial wall consists of the fascial capsule investing the inferolateral wall of the bladder and of the inferior wing of the hypogastric sheath and more dorsally of the forward extension of the hypogastric root. The

Fig. 11. A further step in the dissection shown in Figure 10. The ventral and dorsal layers of the presacral wing have been separated from one another to expose the pelvic ganglion which is enclosed in the space between the two layers.

inferior vesical vessels and their various branches, as well as the venous plexus of the bladder and the ureter are located in this wall. The inferior hypogastric wing separates the space from the vesicovaginal space (Fig. 9) when the beam of a flashlight is thrown into this latter space, it can be seen in the space of Retzius as it shines through the inferior hypogastric wing.

The floor of the space (Fig. 3) is made up by the fascia endopelvina differentiated in front into special vesical ligaments the medial and lateral pubovesical ligaments and the lateral true ligament of the bladder. It extends as far dorsally as the ischial spine and forms an investment of the aponeurotic fibers of the three ligaments and in the female hides from view the portio cardinalis (Fig. 4) of the levator ani. Cutting through this fascia between the ischial spine and the dorsal end of the cardinal portion creates access to the retrorectal space and the dorsum of the rectum. Also the autonomic pelvic nerves can be reached in this way (Fig. 10) as will be shown later on.

SURGERY GYNECOLOGY AND OBSTETRICS

The roof of the space is formed by the superior hypogastric ring (Fig 3) which contains the umbilical artery and its superior vesical branches (Fig 6). The roof excludes the round ligament of the uterus and the ovarian vessels in the female (Fig 6) and the ovary deferns in the male (Figs 6a and 6b) from the space of Retzius.

The dorsal wall of the space is formed by the hypogastric root (Figs 3 and 4) this contains the anterior division of the hypogastric vessels the visceral branches of these vessels and the ureter and seals the space off against the retrorectal space and the rectum. Caudally this wall ends in the easily palpable inferior vesical arch (Fig 4) which arises laterally from the ischial spine and conveys the inferior vesical vein and artery from and to the inferior hypogastric wing.

THE PELVIC GANGLION

The pelvic ganglion while it has received many excellent anatomical descriptions—the most recent one by Curtis, Anson Ashley and Jones (8)—and while it plays a major rôle in the control of the physiology of the pelvic viscera, is nevertheless seldom mentioned or considered in any way in descriptions of surgical procedures, an indication that our anatomical accounts of this structure do not yet lend them selves to the use by the practitioner. We have studied the topography of this anatomical entity from many different angles and in respect to several of the most frequent surgical procedures but are as yet unable to present this subject in a way easily applicable during the various pelvic operations. We have made several observations, however which will be recorded here.

In some subjects it is possible to display after removal of the loose connective tissue between the dorsal capsule of the rectum and the parietal fascia a special sheath the pararectal sheath which arises from the parafascia along a line corresponding to the anterior sacral foramina. This sheath contains between its two layers the pelvic autonomic nerves, conveying them to the presacral sheath with which it fuses. In the female cadaver described here only parts of such a sheath (Fig 10) could be displayed. After reflecting

the presacral sheath (Fig 10) forward, the individual nerves could be easily dissected. The inferior hypogastric nerve (see Curtis, Anson Ashley and Jones 8 for nomenclature), which was only loosely embedded in the dorsal leaf of the presacral sheath had been dissected out to the point where it received two branches from the second sacral sympathetic ganglion. Both the sympathetic and the parasympathetic branches are seen in Figure 10 as they pass, from their origins, laterally and toward the presacral sheath piercing the dorsal leaf of the sheath and entering the space between the two leaves of the sheath.

The further course of these nerves is shown in Figure 11. The presacral sheath was split into its dorsal and ventral leaves was split which succeeds easily if one begins with raising the ventral capsule of the rectum. The ventral leaf was carefully lifted away from the place where the presacral sheath arises from the hypogastric root. The peritoneum of the rectovaginal pouch (Fig 10) was also cut away as it obstructed the view of the illustrations of the nerves but the most caudal portion of the rectovaginal septum is still in place. By these manipulations the pelvic ganglion is exposed as it lies in the space between the two leaves of the presacral sheath close to where this sheath arises from the hypogastric root and where it is joined by the lateral extension of the rectovaginal septum.

The main extension of the ganglion, i. e. its longitudinal diameter is from cranial to caudal. A finger thrust laterally either into the prerectal (Fig 7) or retrovaginal (Fig 8) space would arrive just about at the caudal end of the ganglion. As it lies sandwiched between the two leaves of the presacral sheath medial to the hypogastric root it cannot be reached through the lateral compartment of the space of Retzius. If during a hysterectomy in the female or a cystectomy in the male the presacral sheath is left intact the pelvic ganglion will not be injured. If in making access to the retrorectal space from the lateral compartment of the space of Retzius (see the rubber tubes x and y in Figs. 5 and 10) the finger is pushed into the retrorectal space along the route indicated by the cranial tube x it

will be stopped by the sympathetic and parasympathetic nerves (or the pararectal sheath if that is present) to penetrate sufficiently far medially to reach the rectum the finger or the instrument must be given a caudal direction in order that it may slip through underneath these nerves (see Fig 10)

While the pelvic ganglion receives the hypogastric nerve at its cranial end and the sympathetic and parasympathetic branches at its dorsomedial margin it gives rise to the branches of distribution at its ventrolateral margin and at its caudal end. We have not followed these branches to their terminations. The origins of many of them are seen however in Figure 11 they are joined in their course by a direct branch from the inferior hypogastric nerve. Thus as well as the ventral branches of the ganglion pass into the inferior hypogastric wing evidently to be distributed to the uterus, vagina and bladder. From the caudal end of the ganglion two stout nerves took origin which were seen passing caudally between the rectal musculature and the ventral capsule of the rectum. An arrangement very similar to the one described here was found in several male cadavers.

SUMMARY

1 In the dissection of the pelvis of an adult female supplemented by the dissection of several other pelvis the following components of the visceral endopelvic fascia were studied (a) the hypogastric sheath (b) the fascia endopelvina, (c) the cardinal ligament

2 From the hypogastric root three fascial wings a presacral an inferior and a superior wing take origin. Each of these represents a well defined and easily demonstrable double layered fascial membrane of considerable firmness

3 The presacral wing is associated with the rectum the superior and inferior wings with the bladder

4 The presacral wing absorbs the superior hemorrhoidal sheath furnishes the capsule of the rectum contains the pelvic ganglion between its two layers and in combination with the hypogastric root seals the retrorrectal space off against the lateral compartment of the space of Retzius

5 The superior hypogastric wing constitutes the roof of the lateral compartment of the space of Retzius conveys the superior vesical arteries to the bladder and excludes the vas deferens round ligament of the uterus ovaries and ovarian vessels from the space of Retzius.

6 The inferior hypogastric wing represents one of the major anchorages of the bladder. It conveys the inferior vesical vessels and the ureter

7 Opposite the ischial spine the inferior hypogastric wing is firmly attached to the pelvic wall by the inferior vesical arch through which the inferior vesical vessels are passing on their way between the root and the inferior wing of the hypogastric sheath. Through the inferior vesical arch the bladder is moored to the pelvic wall in the region of the ischial spine.

8 The cardinal ligament arises from the medial side of the inferior hypogastric wing located at a point which is situated more than an inch ventral to the ischial spine. The place where the cardinal ligament is moored laterally to the pelvic floor does not lie opposite the ischial spine but more than an inch ventral to it where the fleshy and aponeurotic fibers of the portio cardinalis a part of the levator ani especially differentiated for that purpose in the female pass from lateral to medial into the inferior hypogastric wing

9 The fascia endopelvina (together with its ventral differentiations the medial and lateral pubovesical ligaments and the lateral true ligament of the bladder) is attached laterally to the pelvic floor along the white line of the fascia endopelvina. To its medial margin are attached like the leaves of a book four (three in the male) leaflike structures the inferior hypogastric wing the lateral fascial wing of the vagina the rectogenital septum and the lateral wing (caudal portion of presacral sheath) of the rectum

10 The lateral compartment of the space of Retzius does not extend as far dorsally as the rectum. At the level of the ischial spine it is sealed off against the rectum by the root of the hypogastric sheath

11 Through the floor of the lateral compartment of the space of Retzius subperitoneal access can be created to the rectum

SURGERY GYNECOLOGY AND OBSTETRICS

12 The rectogenital septum by its attachments laterally to the fascia endopelvina and presacral wing partitions off the subperitoneal space of the pelvis minor into two compartments a rectal and a urogenital

THE HETEROLOGOUS GROWTH OF CANCER OF THE HUMAN PROSTATE

MICHAEL S HOVENANIAN M D and CLYDE L. DEMING M D F.A.C.S.,
New Haven Connecticut

THE growth of human cancer in an alien host offers an experimental approach to the study of the biological activity of malignant tissue. Human prostatic cancer in particular presents a type of malignant growth which may be investigated from the point of view not only of autonomous growth but also of endocrine factors. Previous experimental work on prostatic cancer has been limited to three methods of investigation tissue culture *in vitro* the effect of hormones on the prostatic gland of animals and the stimulation with chemical carcinogens of susceptible strains of laboratory animals. Each of these methods has added knowledge but the secret of causation and the cure of prostatic cancer have not yet been discovered. The object of this paper is to present for the first time the results of heterologous transplantation of carcinoma of the human prostate. This research also includes observations on the effect of hormone stimulation and the biologic activity of the enzyme acid phosphatase in animals with human prostatic cancer growing in the anterior chamber of the eye.

The tissue culture phase of the experimental work was stimulated by the demonstration in 1907 by Ross G Harrison that normal frog tissues and cells could be cultivated outside the organism. Three years later Carrel and Burrows (3) using a modified and improved method of tissue culture, first observed the growth of human cancer cells *in vitro*. In 1917 Burrows, Burns and Suzuki (1) cultured tissues from cancers of the human bladder and prostate and studied the biologic changes which take place in cells outside the body.

From the Department of Surgery Section on Urology and the Department of Pathology Yale University School of Medicine, and the New Haven Hospital.

This work has been supported by grant from the Connecticut Cancer Society Incorporated, and appreciation for this aid is hereby expressed.

Burrows and Kennaway (2) attempted to produce cancer of the prostate in mice by the use of hormones. They observed that long continued estrogen injection caused squamous metaplasia of the prostatic epithelium but no true adenocarcinoma of the gland resulted. Van Wagenen noted fibromuscular hyperplasia in the stroma of the prostate of macaque monkeys as the result of stimulation with large doses of estrin. Moore (8) reviewed the experimental problem of the production of cancer of the prostatic gland by hormones and concluded that in no instance had true adenocarcinoma resulted after the administration of either androgen or estrogen.

Working with the carcinogen benzpyrene Moore and Melchionni (9) caused squamous metaplasia of the prostate in rats after the injection of the chemical into the gland. Dunning, Curtiss and Segaloff induced squamous cell cancer of the prostate in two inbred strains of rats by injection of methylcholanthrene into the prostatic gland and found that these cancers when transplanted to the subcutaneous tissues metastasized to the lungs and skeletal system.

In 1935, Heckel and Kretschmer transplanted homologously normal rabbit prostate into the anterior chamber of the eye stimulated the transplants with pituitary like hormones and obtained growth of the prostatic transplant. More recently the successful heterologous transplantation of human cancers into the anterior chamber of the eye of alien hosts by Greene suggested a new experimental approach to the cancer problem.

MATERIALS AND METHODS

Guinea pigs were employed as the alien hosts in this investigation and the specimen for transplantation was inoculated into the anterior chamber of the eye under sterile precautions. A frozen section of the original

specimen was made before transfer to identify the tissue as a true cancer and to allow the experimenter to choose areas bearing relatively more cancer cells for transfer. The technique of an anterior chamber transplant was

easily carried out. Using surgical precautions, the eye of the animal was anesthetized with a drop of 5 per cent cocaine and the anterior chamber was opened at the corneoscleral junction by a quick stab with a corneal knife. A

small fragment of tissue measuring about 0.5 millimeter in diameter was then introduced into the anterior chamber by means of a trocar. The tissue was guided to the lower angle of the iris by a blunt instrument. No further care was necessary and the corneal incision healed rapidly.

CASE HISTORY

The tissue used in this heterologous transfer was removed from a metastatic lesion of cancer of the prostate involving the left vas deferens. In July, 1945 the patient, a 69 year old lawyer, was admitted to the hospital because of progressive diminution in size and force of the urinary stream. The family history was significant in that the patient's father had died at the age of 55 of cancer of the throat. The rectal examination was characteristic of an extensive malignant prostatic lesion. There had been no weight loss, nor was there any evidence by x ray of

bone metastases. Serum acid phosphatase was 6.95 King Armstrong units.

Since the prostatic lesion was too extensive for total resection it was decided to establish a histological diagnosis and then to treat the patient by means of estrogen therapy. Perineal biopsy revealed an adenocarcinoma of the prostate gland characterized by irregularly growing sheets and strands of cuboidal cells invading the connective tissue (Figs 1 and 2).

The patient tolerated estrogen badly and although he was on a dosage of 1 milligram daily took it irregularly during the year lost weight and was generally unhappy. He did not develop any metastatic pain for 9 months. In May, 1946, 10 months after he was first seen a metastatic x ray series revealed extensive bony metastases involving the lumbar and sacral regions. A cystic mass the size of an egg had developed in the region of the left vas 3 centimeters above the testis. Serum acid phosphatase at that time was 4.2 King Armstrong units. The patient consented to castration and the removal

of the inguinal mass. This tumor proved to be a metastatic lesion from the prostate. It was composed of cells arranged in gland-like formation, with hyperchromatic nuclei, pink-staining cytoplasm, and many mitotic figures. A portion was utilized for ca pig transfer (Figs. 3 and 4).

Castration did not relieve the patient of his back pain, but when the estrogen dosage was raised to 15 milligrams daily the pain disappeared. At the present time this dosage is still being administered to the patient and he seems to be in fairly comfortable condition.

TABLE I.—RESULTS OF HETEROLOGOUS TRANSPLANTATION OF HUMAN PROSTATIC CANCER INTO THE EYES OF GUINEA PIGS

Generation	Number of pigs		Number of takes		Takes per cent	
	Male	Female	Male	Female	Male	Female
First	7	5	5	1-*	71.4	
Second	6	4	2	1-*	25-	
Third		5	8	0	16.6	
Fourth					33.3	
Fifth	6	0			14	100-
Sixth	7	1†		†	47	6
Totals	68	16	30			

*Initially "takes" but within 10 days regressed.
 †Received 5 mgm. testosterone daily for 35 days starting with the day of transfer

These details are presented to show the course of a vigorously growing prostatic malignancy

RESULTS

The first transfer was made on August 13 1946 at which time 12 guinea pigs were inoculated 7 male and 5 female. The usual course of an anterior chamber transfer ensued. The primary period of foreign body reaction was followed by a clearing of the chamber in 6 to 7 days and then rapid vascularization of the transplanted tumor. In 2 to 3 weeks growth was usually evidenced by increase in size and the presence of healthy pink coloration of the new tissue growth. On the average the latent period between transfer and growth was 15 to 20 days although the period became successively shorter in later generations. When the eye was half or more filled with tumor growth the animal was sacrificed and part of the transplant was transferred to another generation of animals. In 6 serial generations of transfer a total of 84 animals were used 68 male and 16 female. Throughout all the generations the transfer the cellular morphology seen in the parent human tumor was maintained. The stroma of the transfer represented the result of the guinea pig reaction to a foreign tissue but the actual cancer cells were a reproduction of the original human tumor cells. These cells reproduced the tumor histologically but biologically differed in that there was a recession of production of acid phosphatase enzyme (Figs. 11 12 13, and 14)

TABLE II.—RESULTS OF HORMONE STIMULATION AND CASTRATION OF GUINEA PIGS WITH TRANSPLANTED HUMAN PROSTATIC CANCER

Generation	Number of pigs		Testosterone stimulated		Controls		Castration		Takes after castration	
	M	F	M	F	M	F	M	F	M	F
Third	3	5	4*		4					
Fourth	0			2*						
Fifth	6			2						
Sixth	7		2*	1			4			
Totals			6	3	4					

*Stimulation with 5 mgm. testosterone daily for 30 days with equal local results.
 †Stimulation with 5 mgm. testosterone daily for 35 days.

The results of serial transfers to the anterior chamber of the guinea pig are shown in Table I

A Hormonal factors During the first two serial generations of heterologous transfer natural growth was allowed to take place. Beginning with the third generation castration and androgen stimulation were added to the experiment. These results are summarized in Table II. Successful "takes" occurred in 33 animals, slightly less than one-half but only 1 of these "takes" occurred in a female animal. This female guinea pig was stimulated with a tremendous dosage of testosterone 5 milligrams daily for 35 days starting with the day of transfer.

Of 8 animals with successful takes in the third generation 4 were stimulated with testosterone 1 milligram daily for 30 days but no particular increase in rate of growth occurred as compared with 4 animals with successful "takes" used as controls. The eye filled up one-half to full in these cases, but the controls grew just as fast, and no definite conclusions could be drawn as to the positive effect of testosterone. Examination of microscopic sections of the testes of the animals stimulated with androgen did not show any changes. Two male animals in each of the fourth and sixth generations were castrated prior to transfer of the tumor. None of these male castrated developed successful takes from the transplanted tumor. In 15 female guinea pigs inoculated with human prostatic cancer not 1 animal developed a successful "take". When

testosterone in massive doses 5 milligrams daily for 35 days starting with the day of transfer was given a successful take did occur in a female guinea pig. Microscopic examination of the endocrine organs of this animal did not reveal any marked cellular changes. The ovaries had formed follicles and corpora lutea, and the pituitary and adrenals appeared normal.

The fact that the prostatic tumor did not grow in female animals and could not be transferred to castrated males took on a significant meaning since previous attempts to transfer a metastatic node from a proved case of carcinoma of the prostate had failed, although transplants seemed to remain alive for some time. On reconsidering these facts it was deduced that all the animals used in this previous unsuccessful transfer were females.

B. Enzyme factors. Serum acid phosphatase levels were determined in normal guinea pigs and those having prostatic cancer transplants growing in the anterior chamber. This technique was easily performed by anesthetizing the animals and performing cardiac paracentesis. The heart blood was then measured

for the presence of phosphatase in King-Armstrong units. The blood phosphatases for normal and tumor bearing animals did not differ as shown in Table III.

The serum acid phosphatase level of guinea pigs was not affected by the presence of human prostatic cancer growing in the anterior chamber of the eye. The results obtained from both normal and tumor bearing animals varied greatly but no marked difference resulted from heterologous transplantation. Phosphatase stains on sections of transplants in the fourth and sixth generations failed to show the presence of enzyme. The regression of prostatic acid phosphatase enzyme in heterologously transplanted human prostatic cancer as shown by negative phosphatase staining reaction corroborated the finding of absence of elevation of blood serum acid phosphatase reading in tumor bearing animals. The transplanted cancer therefore must have undergone a change in biological activity in the guinea pig although the morphological structure of the tumor remained the same as the original human cancer.

An attempt was made to determine whether the enzyme acid phosphatase was produced by the cellular nucleus or cytoplasm. Human benign and malignant prostatic tissue was first emulsified in a Ten Brock homogenizer and then centrifuged at high speeds to isolate the cell nucleus from the cytoplasm. These constituents were then stained for phosphatase content. The amorphous cytoplasm of centrifuged prostatic cellular material gave a much heavier stain for phosphatase than did the nuclear portion of the cell, indicating that the greater part of the enzyme acid phosphatase was a component of the cytoplasm of the prostatic cell.

COMMENT

The growth of human prostatic cancer in an alien host proves conclusively that this cancer is an autonomous growth. The results of heterologous transplantation of human prostatic cancer using the guinea pig as the alien host have indicated that this cancer is influenced by hormonal factors within the animal. Lack of growth of transplanted prostatic cancer in female animals implies that the male hormone must be present for the growth of this tumor.

Similarly, human clinical experiences have revealed that cancer of the prostate has not been found in eunuchs. No cellular changes were found in the testes of guinea pigs stimulated with testosterone. The endocrine system of a female guinea pig stimulated with massive doses of androgen did not show any cellular changes. Testosterone or one of its constituents therefore, must be present for the growth of prostatic cancer in male animals, but this experimental study suggests that the actual amount of the substance is not important, since control animals grew tumors just as rapidly as testosterone stimulated males.

The inherent ability of prostatic cancer cells to produce the enzyme acid phosphatase disappeared on heterologous transfer. The absence of the enzyme activity in tumor growing in the guinea pig eye was corroborated by the finding of no elevation of blood phosphatase levels and by the results of tissue stains. The enzyme acid phosphatase is a product of cellular metabolism and is produced by both nucleus and cytoplasm. Although the enzyme activity of the prostatic cell changed on heterologous transfer the transplanted tumor retained its autonomy and was transferable to succeeding generations. One can therefore postulate that the all important part of the cell in malignant growth is the nucleus. It is the cellular nucleus then, which is the portion of the malignant cell that does not alter its character but keeps on growing wildly in spite of the alien host or environment. This cellular nucleus must hold the key to the answer why malignant cells set up an autonomy and characteristic trait of disordered, uncontrolled cellular growth and metabolism.

Heterologous transplantation presents a method of investigation of human cancers to elicit the effects of biologic agents, carcinogens, hormones and perhaps even cancer lytic substances upon malignant growth.

CONCLUSIONS AND SUMMARY

- 1 Cancer of the prostate gland has been successfully transplanted heterologously in

guinea pigs for the first time demonstrating the autonomous nature of this cancer.

- 2 By serial transplantation of this malignant tumor it has been shown that prostatic cancer is under the influence of endocrine factors.

- 3 When transplanted heterologously in male castrated guinea pigs, human cancer of the prostate did not grow. Similarly in human clinical observation cancer of the prostate has not been found in eunuchs.

- 4 Stimulation of female guinea pigs with small amounts of androgen did not affect the growth of transplanted prostatic tumor but stimulation of a female with massive doses aided in establishing a successful take of prostatic cancer.

- 5 Carcinoma of the human prostate heterologously transplanted in guinea pigs lost a fundamental biological activity, the production of the enzyme acid phosphatase. This fact was demonstrated by the absence of elevation of blood phosphatase level in tumor-bearing animals and absence of stain for phosphatase in sections of tissue removed from the guinea pig eye.

- 6 Heterologous transplantation of human prostatic cancer has indicated that the cellular nucleus holds the key to the biological activity of malignant cells which have become autonomous, disordered in growth and uncontrollable in cellular metabolism.

STUDY OF URETERAL BLOOD SUPPLY AND ITS BEARING ON NECROSIS OF THE URETER FOLLOWING THE WERTHEIM OPERATION

JOHN P. MICHAELS M.D., New Orleans, Louisiana

THE radical, or Wertheim operation for carcinoma of the cervix uteri occasionally results in serious damage to the ureter, necrosis and fistula formation occurring in 6 to 10 per cent of cases (15 57 23). Meigs (33) the champion of the Wertheim operation reported 12.3 per cent spontaneous ureteral fistulas, in his last series published. However, this figure has been sharply reduced in most recent cases in which he carefully avoided injury to the major ureteral vessels. Such operative mortality and morbidity but has often necessitated nephrectomy or other surgical procedures which in themselves may be serious. Anspach in reviewing the problem of cancer of the cervix since the introduction of radium therapy in 1912 predicts that despite the great improvement in results from surgery the morbidity from ureteral injury will still remain. Lynch (25) remarks that the radical operation is justifiable when it can be done not only with little or no mortality but with the avoidance of fistula and other major morbidity. Meigs (32 33) in spite of his zero mortality rate thinks the greatest drawback to the operation is ureteral injury and insists that its incidence must be lowered. Most authors have reported that this complication is primarily brought about by an interference with the blood supply of the ureter incurred during the operation. Meigs (33) in his most recent report on the Wertheim operation states that with better understanding of the ureteral blood supply fewer ureteral fistulas would develop. It is hoped that a study of the ureteral blood supply may bring to light some facts which may aid in reducing this serious complication.

It seems pertinent that a brief account of the genesis of the Wertheim operation and a review of the more recent literature concerning it be included in this discussion.

In 1878 Freund operated by the abdominal route on a patient who had carcinoma of the cervix. His procedure became the basis for all successful operative methods for this malady. In 1895 Clark, Ries and Rumpf suggested a more radical procedure which included removal of the pelvic lymph nodes. Wertheim's extensive series is credited with popularizing the operation which since has been known as the Wertheim operation. This operation consists of the removal through the abdominal route of the uterus and adnexa and by the use of clamps as much of the vagina as possible. The ureters are dissected and freed bilaterally to enable the operator to remove as much parametrium as feasible and finally to extirpate all enlarged pelvic lymph nodes. It is during the dissection and freeing of the ureters along their courses through the parametrium that injury in one form or another may occur. Since this study is limited to necrosis and fistula formation as a result of injury to the blood supply of the ureter those injuries due to cutting clamping or ligating the ureter will merely be mentioned although Bland Fenner and Adams have shown that all types of injuries to the ureter are very frequent complications of this type of operation.

Until recently in this country the mention of the Wertheim operation brought forth strong protest from the majority who are called to treat carcinoma of the cervix. Many have considered and some still hold that the percentage of cure resulting from this formidable operation is not high enough to

From the Departments of Anatomy and Gynecology School of Medicine, Tulane University of Louisiana. Abstract of thesis submitted to the faculty of the Graduate School Tulane University of Louisiana in partial fulfillment of requirements for the degree of master of science in Gynecology and Obstetrics. This study was aided by grant from the Watson Research Fund.

compensate for the inherent high mortality and morbidity rate. Henry Schmitz, once wrote "If Shakespeare were alive today he might have written 'The evils of carcinoma operations live after them the good is oft interred with their bones'."

Meigs (32, 33, 34) dissatisfied with the results obtained after radiation therapy became interested in Taussig's work (51, 52, 53) on iliac lymph adenectomy combined with radiation. He decided to employ radical surgery in selected cases, in the form of the Wertheim technique, utilizing Taussig's method of lymph node dissection. His rationale is based on six points: (1) If the cervix has been removed there is no chance of a recurrence in it. (2) If the cervix has been removed no cervical cancer can regrow in it as a recurrence. (3) Cervical cancers of the cervix are radioresistant. (4) There will be less damage to the bowel if surgery is undertaken. (5) Patients with lymph node metastases can be cured by surgery in some instances. (He does not believe it possible to cure by means of radiation metastases in lymph nodes deep in the pelvis.) (6) With the cervix removed it cannot become the nidus of a recurrence or a new tumor.

Buske and Cantrell report that 20 per cent of stage I and 30 per cent of stage II cases are not cured by even the most competent and skilled radiotherapist but they suggest that possibly these figures may be reduced by improvement of radiation therapy. These authors state that "Granted that irradiation therapy cannot sterilize lymph node metastases, Meigs has saved 9 cases. However in accomplishing this, 20 patients have had to have Wertheim operation to save 3 that could not be saved otherwise. Meigs (35) has performed 100 Wertheim operations without a single operative death. His mortality rate is the lowest ever reported for this procedure and is a far cry from the high primary mortality rate that one finds reported in the earlier accounts. According to Martzloff there is a third era probably at hand, a period of a more rational employment of surgery or irradiation or both, to serve until such time as some more fundamental solution of carcinoma treatment is developed. Martzloff's statement is supported by a survey of the recent literature."

Counsellor reports that the Mayo group has done a total of 113 Wertheim operations in the last 10 years, with results approximating those of Meigs. They feel that the Wertheim procedure should be given consideration in selected cases. McMurray believes that the entire armamentarium available for therapy must be utilized and that there are definite indications for x ray, radium, and surgery. Morton (37) reports 100 cases of carcinoma of the cervix treated surgically by the Wertheim technique with over all primary mortality of 6 per cent. Of these cases 78 patients were operated on in the last 20 years with a mortality of 2.7 per cent (a rate lower than in total services which include the earlier operations). He (38), also does a pelvic lymph adenectomy along lines set forth by Taussig (51). Lynch (26, 27) and Taussig (53) advocate the Wertheim operation in early cases. Weaver (54) subdividing Group I of the League of Nations combined with Martzloff's or Broder's cellular classification, recommends a combination of surgery, x ray, and radium in these early cases. Bonney (4) Goodwin Schlink and Chapman and Maguire, all of the British Empire, are among the current proponents of surgical treatment.

It is apparent that many surgeons are cautiously returning to surgical therapy either alone or in combination with radiation. This we believe is the result of two factors: (1) The mortality rate has now approached a figure compatible with the operation's continued use. This has been the result of proper and careful selection of cases for surgery improved surgical technique, better anesthesia, the use of preoperative radiation to sterilize the cervix, transfusions of whole blood and plasma and the sulfa drugs and the antibiotics. (2) A desire to better the current percentage of salvages by utilizing every available means of treatment.

Skinner sums the whole problem of treatment of cervical carcinoma as it stands today by stating that "we now enter into a desperately competitive era of research, pathological studies, irradiation, surgical liberties, tempered only by mortality, morbidity statistics, impeded by unpleasant hospitalization, and most anesthesia progress."

SURGERY GYNECOLOGY AND OBSTETRICS

important, a public response to lay education and increasing support to lay activity

ETIOLOGY OF SPONTANEOUS URETERAL FISTULAS FOLLOWING THE WERTHEIM OPERATION

Concerning the etiology of spontaneous fistulas following the Wertheim operation one may note that these have occurred in practically every series reported. Wertheim felt sure that they were due to a disturbance of the blood supply of the ureter leading to a subsequent necrosis of that organ. Weibel noted that these fistulas occur in the easy operations as well as in the difficult ones where extensive isolation of the ureter must be carried out. Since these fistulas appear at the place where the ureter runs through the parametrium, he postulates that this constitutes a *locus minoris resistentiae*.

The majority of reports indicate that, as Wertheim postulated, the main factor is a disturbance of the blood supply of the ureter. However not all authors are of this opinion. Frommolt (14) believing the vascular anastomosis of the ureter to be so efficient that injury of its blood supply is of no great moment, blamed necrosis and subsequent fistula formation on direct injury to the ureteral wall. Weibel believed that there may be several factors at work ligatures too near the ureter held that postoperative kinks of the ureter are more important than injury of the blood supply. Some German authors felt that if necrosis were due solely to a destruction of the blood supply to the ureter the incidence of necrosis and fistula formation should be very high because most surgeons stripped the ureter of its incoming blood supply for great distances. Fitel, at Wertheim's request, studied the upper part of the ureter and showed that the medial side from the aorta, common iliac, and internal iliac arteries. The lower part was supplied by vessels lateral to the ureter i.e. uterine and vesical arteries. He therefore deduced that to avoid injury to these vessels when exploring the pelvic ureter the perineum above should be incised laterally the incision being carried down on the medial side of the ureter. Sampson (44) noted that al-

though Wertheim following Fitel's suggestion was apparently preventing necrosis by the method of incision, by remaining medial to the ureter he also ran the risk of leaving carcinoma parametrium behind.

Sampson (44) following injection studies of the ureteral vessels in cadavers and experimental studies on dogs came to the conclusion that the protection of the periureteral sheath and its enclosed periureteral vascular anastomosis was of more importance than was the avoidance of injury to the main vessels themselves. We believe that Sampson and Fitel were both correct in that it is of the utmost importance to preserve both the periureteral plexus of vessels and the ureteral artery themselves and in particular the main artery of the ureter the less the chance for necrosis whether the ureteral wall has been injured or not. There may well be accessory etiological factors which play a part in certain cases, but such instances are believed to be in a minority. Sampson (45) considers the following factors as possibilities in addition to injury to the periureteral sheath and its vascular plexus: (a) ligation of vessels supplying the formation of adhesions which splint the ureter (exudates, gauze packs, infection cauterization of the ureteral tissue bed, or mass ligatures (c) pressure on the ureter (d) stricture below ureteral injury (e) general lowered resistance of the patient.

THE BLOOD SUPPLY OF THE HUMAN URETER AND ITS RELATION TO URETERAL FISTULAS

Anatomical texts (10 17 46) mention the blood supply of the human ureter in one or two brief sentences. A. V. Haller was the first to give an adequate description of the ureteral blood supply. He recognized that the upper third of the ureter was supplied by the renal artery the middle third had an artery of its own and the lower third received branches from the vesical arteries and the uterine arteries. A review of the literature (12 15 19 40 42 44) reveals that there have been but few who have studied this subject in any detail. When the present study was undertaken it was thought that ordinary dissection of the

From the above chart one may conclude that the main blood supply to the ureter may be multiple; their source being either the abdominal aorta, common iliac, or hypogastric arteries or, combination of these. The main blood supply may thereby be endangered in freeing the ureter through its pelvic course or during pelvic lymphadenectomy. The ureteral branches from the renal, uterine and vesical arteries are constant but short local branches. These, however, play an important part in the peritoneal anastomosis. Ureteral branches from the internal spermatic (ovarian) arteries are inconstant and are generally small twigs.

cadaver would supply the needed information. However, difficulties were encountered in exposing the minute vessels, and after dissecting several adult subjects this was abandoned. It was then decided to work on fresh stillborns using an injection mass to facilitate identification and dissection of blood vessels. Since colored synthetic liquid latex has been used to study the blood supply of various organs and tissues with great success it¹ was chosen for this study. As shown by Lieb (24) the substance penetrates even the smallest vessels. Such injected preparations lend themselves to corrosion and clearing.

The apparatus used for perfusion was a simple one patterned after that described by Narat, Loef and Narat consisting of two pressure bottles with a mercury manometer hooked in by means of a Y tube to allow for pressure readings. Perfusion of the specimens was carried out through the descending thoracic aorta, tap water being used at 50 millimeters of mercury for 1 hour then 100 to 120 millimeters from 4 to 6 hours. After difficulty

was experienced with leaks in the vascular system in the first two specimens the abdominal cavity was subsequently left unopened except for a small slit in the left lower abdominal quadrant. This not only acted as an escape for the intraperitoneal accumulation of fluid but also allowed a small segment of the small intestine to be drawn out and observed during the injection of the liquid latex thus noting the progress of arterial filling. During perfusion the specimen became notably swollen but after having been placed in a refrigerator overnight the edema practically disappeared.

A small compressor motor was used to inject the mass, at a pressure of 120 millimeters of mercury. The injection was done as soon as the specimen had returned to room temperature. All injections were done through the descending thoracic aorta and any leaks which had not been previously cared for were immediately stopped by applying a pledget of cotton moistened with a few drops of acetic acid. Following the injection the specimen was placed in a large jar of 5 per cent acetic acid and 10 per cent formalin, the abdomen

¹Nooprene.

SURGERY GYNECOLOGY AND OBSTETRICS

being opened to admit the fixing fluid. After 12 to 24 hours in this medium the specimen was removed and the ureteral blood supply was dissected out with the aid of a magnifying loupe. The ureteral vessels in the fetus are extremely small and delicate but their consistency after injection allowed for a satisfactory dissection. Though no attempt was made to corrode these specimens two block dissections of the abdomen and pelvis were cleared in wintergreen oil to afford a closer study of these fine vessels.

A total of 16 ureters were studied in 8 specimens but due to a seemingly incomplete injection of one only the results as found in 7 (see Table I) Before presenting the detailed findings in 2 of these specimens a general description of the blood supply to the ureter as found during this study will be given.

The ureter receives its chief blood supply from what may be called long arteries which arise either from one or more of the following major vessels: the lower end of the abdominal aorta, just before its bifurcation; the common iliac artery or the hypogastric artery. Where the origin is from the common iliac or hypogastric the ureteral arteries invariably arise from the medial side of these vessels and cross the artery of origin laterally to reach the medial side of the ureter where it divides into a T with an ascending and a descending branch which may course for practically the whole length of the ureter. These longitudinal branches are of the same caliber as the ureteral artery and are found in the loose adipose areolar tissue capsule of the ureter. These ascending and descending primary branches anastomose with similar branches above from the renal, spermatic or ovarian arteries and below with similar branches from the uterine and vaginal arteries. In addition to branches on the inferior and occasionally the superior iliac and middle hemorrhoidal arteries. In several instances the branches from the superior spermatic (ovarian) uterine, vaginal, and the inferior vesical arteries may be considered as arteries which mainly supply that part of the ureter in their immediate vicinity. In several cases the main blood supply to the ureter was found to be multiple.

As first noted by Fitel the arteries to the upper portion of the ureter (renal, aorta, common iliac, and hypogastric) reach the ureter on its medial side while those supplying the terminal portion (uterine vaginal and vesical branches) reach the ureter on the lateral side. The long ureteral arteries in turn give off many small branches which ramify around and over the ureter anastomosing with each other on all sides above and below from the renal pelvis to the bladder. These secondary branches in turn give off many minute branches which pierce the muscular coat of the ureter. Details of the anastomoses of these terminal branches were not determined but it is evident as Sampson (44) has reported, that anastomoses of this third set of arteries are not as abundant as in the other two sets. Serial sections of ureters obtained from two adults at postmortem examination during this study revealed a rich blood supply of the muscularis and mucosa but no definite anastomosis of these vessels could be determined. Frommolt (15) however claims that these fine branches anastomose with each other in the muscular coat of the ureter. In contrast to the longitudinal branches the secondary branches of the ureteral arteries are quite closely adherent to the muscular coat, and these are not likely to be injured except by direct trauma whereas the primary long ureteral branches may be readily damaged in either dissection of the ureter from the parametrium or during pelvic lymphadenectomy.

It has been demonstrated in dogs (29, 44) and in man, (15, 20, 56) that the ureter may be isolated or stripped for relatively great distances without subsequent necrosis. The safety factor lies in the multiple blood supply to the ureter and the rich anastomoses of the primary and secondary branches of the ureter not only locally but from the kidney pelvis to the bladder. Sampson (44) demonstrated this by studying the efficiency of the ureteral blood supply by injecting a mass through various ureteral arteries. Therefore, if one ureteral artery is destroyed it may be possible for other branches to take over the blood supply. That this is true is not disputed, for in hundreds of Wertheim operations where the ureter has been described as running through the pelvis

Fig. 1 Arterial blood supply of ureters of the male

like a telephone wire following its free dissection relatively few fistulas have developed. However there must be cases of failure of this remarkable collateral circulation due to excessive robbing of blood supply coupled with vasospasm or disturbance by exudates, hematomas, trauma, and other pathological conditions of the secondary vessels of the ureter. There must be cases also in which the finer secondary branches which firmly cling to the ureter are directly traumatized in a limited region; thus may not be evident at the time of operation. Another factor is that carcinoma of the cervix occurs in the later decades of life when the smaller arteries and arterioles may

have become less efficient as a result of changes associated with age.

It is obvious that to guard against necrosis of the ureter it is imperative to minimize damage to the ureteral blood supply during isolation of the ureters in the Wertheim operation. It is not advisable to ligate the internal iliac artery routinely as this may readily predispose to a further cutting down of the blood supply to the pelvic ureter. The branches of the uterine and vaginal arteries must of necessity be destroyed during the operation and the vesical branches are often inadvertently injured because of their positions. The burden may therefore rest with the main ureteral

ine arteries. These longitudinal branches are loosely connected to the ureter and are contained within an adipose fibrous sheet. Secondary branches given off from these primary arteries arborize over the ureter for its entire length and anastomose freely with each other above and below and form a compact perireteral anastomosis from the renal pelvis to the bladder. A third set of arteries is given off from those vessels around the ureter and these in turn pierce the muscularis of the ureter to supply the wall.

6 Prophylaxis is the best treatment for this complication. In addition to a proficient knowledge of the normal and abnormal anatomy of the ureter one must meticulously and gently dissect the ureter from its bed using every caution not only to preserve the perireteral arterial plexus but also carefully to dissect out and preserve the blood vessels to the ureter. These latter vessels are also to be avoided during pelvic lymphadenectomy. The avoidance of other contributing factors such as mass ligation, use of drains too close to the ureter etc. are discussed. A survey of the suggestion of hypogastric block or resection to increase the blood supply to the ureter as an additional prophylactic aid.

HYPERTROPHIC PYLORIC STENOSIS

ARTHUR A. SCHAEFER, M D F.A.C.S., and JOHN ERBES M D Milwaukee, Wisconsin

PYLORIC stenosis is the most common condition requiring surgical treatment in the first few months of life (12). The diagnosis is being made more and more frequently. Ladd (12) states that the operative attack on pyloric stenosis marks one of the greatest advances in abdominal surgery in the last 20 years.

Two hundred and forty-eight cases of pyloric stenosis have been admitted to Milwaukee Children's Hospital between June 1924 and May 1947. The Fredet Rammstedt pyloromyotomy was done on 232 of these and 15 were not operated upon. Sixteen deaths have occurred in this series, 9 of which were postoperative deaths. The 7 other cases were treated medically.

There has been no death during the past 10 years, during which time diagnoses were made and operations performed in 172 infants. We believe that we can point out several reasons responsible for this drop in mortality rate.

INCIDENCE

The majority of cases of pyloric stenosis occur in males. Our series show a preponderance of 65 males to 1 female, or 86 per cent in males. Ladd reported 85 per cent. Fredeen 78 per cent.

Our records show that 1 in 213 children admitted to Milwaukee Children's Hospital had pyloric stenosis. Cranmer estimates that 1 in 400 male infants is affected. Wallgren reviewed the records of all children born in Göteborg, Sweden from 1934 to 1940 and found that among 25,642 children born 102, or 0.4 per cent, developed pyloric stenosis. This is 1 in 250 births. On studying further he found the incidence to be 1 in 770 girls born and 1 in 154 boys born. These figures would not necessarily be significant for this country since it is well known that the disease is common in some races that it is rare in others

and that we represent a mixture of all the races.

Wallgren called attention to Eckstein's report that he observed only 2 children with pyloric stenosis among 50,000 patients treated in the out patient department for children's diseases at Ankara, Turkey, and that the parents of these children were foreign born, also, that a pediatrically trained medical missionary found only one case during many years in the Belgian Congo and that this patient was of French parentage.

There were no negroes in our series. Fredeen reports 1 negro female in 32 cases at the University of Kansas. Romano reports 30 per cent in negroes from the Charity Hospital in New Orleans.

It has frequently been reported that the majority of cases are found in the first born of a family. Our figures bear this out. First born constituted 43 per cent of our cases, second born 21 per cent, third born 16 per cent, and fourth born 5 per cent. One case was the 12th child in the family. None of the first 11 children had been affected.

About half of our cases were breast fed and the other half were artificially fed. We can find no justification of some claims that pyloric stenosis occurs most often in artificially fed babies.

Seventy per cent of the patients in this series were between the ages of 3 and 6 weeks. The youngest was 10 days old and the oldest was 7 months. MacHaffie of Canada reports an infant that was operated on 34 hours after birth. Reports have been numerous of pyloric stenosis in adults (2, 11). The majority of these are diagnosed either in the specimen removed during a subtotal gastric resection for suspected carcinoma, or at the autopsy table.

Our series contained 9 instances in which more than one member of the family was affected with pyloric stenosis. In one family there were 3 cases, 2 boys and a girl. In

From the Surgical Service of the Milwaukee Children's Hospital.

At times it is very difficult or impossible to feel

Ladd Ware and Pickett felt the tumor in over 98 per cent of cases. Brown of Nebraska felt the tumor in 44 per cent of cases. Our records show that a tumor was felt in 63 per cent of cases. However, several individuals with considerable experience were able to feel about 90 per cent in the cases with which they were associated.

DIAGNOSIS

Projectile vomiting is usually the first symptom to call the examiner's attention to this condition. It should stimulate him to inquire into the bowel habits and weight gain of the patient and to seek the peristaltic waves and palpate the pyloric tumor. Occasionally the mother will volunteer the information that she has seen 'knots going across the stomach' but usually the examiner must stimulate the production of the peristaltic waves himself. This is easily done by placing the undressed patient between the examiner and a window or light and giving the patient some water to drink. The peristaltic waves begin in the left upper quadrant and progress diagonally down and across the abdomen above the umbilicus. Usually two waves the size of a half golf ball are evident with a depression between them. The waves cast a shadow into the depression as they move across the abdomen from left to right.

Peristaltic waves are seen in other conditions, such as pylorospasm and therefore are not diagnostic without other accompanying symptoms. Peristaltic waves running from right to left are indicative of large bowel pathology and may be confused with the gastric peristaltic waves which are found in pyloric stenosis.

A palpable pyloric tumor is pathognomonic of pyloric stenosis and is therefore the most important finding for establishing the diagnosis. Occasionally the tumor is easily felt, but usually considerable dexterity and experience are required to palpate even a markedly enlarged pylorus since the majority of patients are hypertonic and crying when first seen in the examining room. Our records show very plainly that the highest percentage of

tumors are felt by those who have the greatest experience and those who make their examination under the proper conditions. The tumor is most easily felt in the manner described by Seeger.

The operator is seated at the right of the examining table and the right hand is used to palpate the abdomen while the left hand is placed beneath the patient to give counter pressure from below. Usually the olive shaped tumor is felt near the midline in the right upper quadrant just beneath the edge of the rectus muscle. It is quite mobile and can sometimes be rolled against the prominent spine. Often its position can be determined by watching the point where the peristaltic waves end.

A palpable tumor is positive evidence of pyloric stenosis. Failure to palpate a tumor is not conclusive proof to the contrary. (10)

During the past few years we have become more and more aware that roentgenologic examination is one of the most important procedures available in the diagnosis of pyloric stenosis. We agree that if pyloric tumors were 100 per cent palpable there would be little value in subjecting the patient to this procedure but in our series the tumor was palpable in only 63 per cent of cases. Series reported in the literature record the tumor as being variously palpable from 24 per cent (17) to 98 per cent (13).

In reviewing the records of 187 cases of pylorospasm seen at Milwaukee Children's Hospital between 1914 and 1947 6 cases were found in which examiners reported feeling the pyloric tumor. In all of these, subsequent roentgenologic examination was done and reported negative for pyloric stenosis. In spite of the negative x ray report, 1 patient was operated upon and a normal pylorus was found at operation.

In 3 other cases examiners reported feeling the pyloric tumor, but no x ray examinations were made before operation. In all of these a normal pylorus was found during operation. One of the 3 later died of septicemia. It is evident, then that our only pathognomonic finding is not 100 per cent reliable.

When properly performed roentgen examination is almost 100 per cent reliable. The

pyloric tumor containing barium casts a typical shadow of the stenosed pyloric canal which is funnel shaped at its entrance and long and narrow through its lumen. This has been described by Heske as a prepyloric narrowing and the string sign. Delayed opening time and gastric retention of barium are helpful in making the diagnosis but the 'prepyloric narrowing' and the string sign give an exact picture of the stenosed pyloric canal which is not simulated by any other condition.

Many authorities object to the use of roentgen examination because of the possibility of aspiration of barium or because of the difficulties that the barium might cause at operation. These same authorities recommend that full formula feedings be maintained during the preoperative period regardless of the vomiting.

We do not believe that the danger of aspiration of barium is any greater than the danger of aspirating vomitus from the periodic full formula feedings recommended during the preoperative period.

In all of our cases the stomach is lavaged after the roentgen procedure and before operation and there has been no difficulty from any residual barium in the stomach.

The x ray procedure is carried out in the following manner:

The patient is given no food for 6 hours to insure that the stomach is empty; then the patient is given 2 ounces of formula barium mixture and the patient is observed under the fluoroscope. Roentgenograms are taken at 5 minutes and 30 minutes in positions determined by fluoroscopy to show the best view of the pyloric canal. This is invariably a right oblique position. If the canal is well visualized in the 30 minute film no more films are taken; otherwise subsequent 1 and 2 hour films are taken until a good view of the canal is obtained.

TREATMENT

The evolution in the surgical treatment of pyloric stenosis is very interesting and its beginning dates back to 1892 when Cordus of Hamburg, Germany, performed the first surgical procedure—a jejunostomy with an unsuccessful outcome (8).

Four methods of surgical treatment have been in use (1). The first and most unsuccessful was the Loreta division of the pylorus in which an incision was made into the anterior wall of the stomach and graduated sounds were passed into the stomach and through the pylorus stretching its lumen. Usually the pyloric mass broke rather than stretched, and the patient died of peritonitis.

The second operation was a simple pyloroplasty advocated by Dent in 1902. A longitudinal incision was made through the tumor extending from the stomach to the duodenum, cutting through all layers including the mucosa. This longitudinal incision was then transformed into a transverse incision by bringing the ends together with sutures in the manner of the Heineke-Mikulicz operation. The mortality rate, however, was too high. Surgeons began doing gastroenterostomy with which many were familiar. Even so the mortality rate was very high.

In 1906 Nicoll began doing a partial pyloroplasty in which only the muscle and not the mucosa was incised. He made a V shaped incision through the tumor at right angles to the long axis and by converting it into a Y increased the diameter of the lumen. This was the first of the submucous pyloroplasty operations.

In 1908 Fredet made a longitudinal incision through the muscle layer not opening the mucosa, and converted it into a transverse incision in order to increase the lumen diameter by bringing the two ends together with sutures.

In 1911 Rammstedt was performing the Fredet submucous pyloroplasty and found that he could not get the ends together because his sutures tore out of the edematous hyperplastic tumor, so he sutured the omentum over the incision and closed the abdomen. The patient got along very well. In 1912 during another operation he incised the pyloric muscle and left the defect uncovered in the manner in which the operation is performed today. The patient made an uneventful recovery. This procedure is essentially the same operation that is universally carried out today and is known as the Fredet Rammstedt pyloromyotomy.

Fig 1 a, left, Diagram of normal pylorus. b Roentgenogram of normal pylorus.

Fig 2 a, left, Diagram of case of hypertrophic pyloric stenosis. b Roentgenogram of same case showing hypertrophic pyloric stenosis.

PREOPERATIVE TREATMENT

Probably the greatest aid in the reduction of operative mortality rated during the past 10 years has been early diagnosis and adequate preoperative care.

Pyloric stenosis is no longer considered an emergency. Operation is frequently postponed 24 to 48 hours in a particularly dehydrated individual while fluids are given to hydrate the patient and to re-establish electrolyte balance. Usually 60 to 100 cubic centimeters of Ringer's solution is given subcutaneously every 6 to 8 hours depending upon the degree of dehydration which is present and upon the size of the patient.

Some writers have used parenteral amino acids preoperatively in particularly malnourished and dehydrated patients either intravenously or subcutaneously and have reported gratifying results. A few years ago the proper

diagnosis occasionally was not made until the patient was marasmic. These patients were given preoperative transfusions together with parenteral fluids. During the past few years it has been routine at Milwaukee Children's Hospital to give the patient a transfusion before leaving the operating room, 10 cubic centimeters per pound body weight of whole blood being given by the multiple syringe method. This transfusion corrects the depleted serum protein and brings the lowered red blood cell count and hemoglobin values up to a satisfactory level, giving the patient an added boost to carry him through the immediate postoperative period until he can care for his own nutritional requirements. We believe that this procedure has been very instrumental in lessening postoperative complications and at the same time in making for an easier convalescence.

Fig. 3. a, left, Diagram of another case of hypertrophic pyloric stenosis. b Roentgenogram of same case.

OPERATION

It is almost universally agreed that the Fredet Rammstedt pyloromyotomy is the operation of choice in the surgical treatment of pyloric stenosis. This operation was used in all of the cases which were surgically treated in this series.

The correct type of abdominal incision to use is still a matter of discussion. Three types of incision were most generally used in this series. Many of the earlier surgeons made no record of the type of incision used so no accurate account can be given. The earliest incision to be used was the right rectus incision which remained popular until Robertson described the gridiron incision in 1940. For about 3 years after that various adaptations of the gridiron incision were used. The most popular of these was Meredith's adaptation in which a regular right rectus incision was used but in which the posterior rectus sheath and peritoneum was opened transversely. In 1943 the majority of surgeons reverted back to the right rectus incision but made it high just beneath the rib margin in order to utilize the liver as a stop-plug to block the intestines from extruding through the wound. After closure of the wound the right lower margin of the liver slides back into place behind the incision and prevents the intra-abdominal pressure from being exerted directly against the incision. This type of incision is most popular today and it has been found that in no case has wound dehiscence or incisional hernias resulted.

The pyloric tumor is usually quite mobile and is easily brought into the abdominal opening. A longitudinal incision is made through the serosa and slightly into the hypertrophied muscle at the superior border which is usually the most avascular area while the assistant holds the duodenum and stomach rotating the pyloric tumor downward to present the superior avascular area. No attempt is made to cut entirely through the muscle, but only through the serosal layer from the stomach to the duodenum separating only the most superficial muscle fibers. The closed points of a small artery forceps are inserted into the incision and spread breaking through the muscle fibers which make up the tumor. This is carefully carried out until the underlying mucosa is freed of the surrounding fibers and bulges through the incision. At the stomach end of the tumor the muscle fibers gradually blend into those of the stomach but at the duodenal end the muscle fibers end bluntly extending into the duodenal lumen in the manner of the cervix into the vagina. It is here that great care must be exercised in separating the muscle fibers, since the closely investing mucosa of the duodenum is easily torn in the process, and if this accident is not detected the resultant leaking will cause peritonitis.

When the incision is made in the avascular area, very little bleeding results. The small amount of oozing can be controlled with warm moist packs. Large bleeders are difficult to ligate in the edematous tumor and occasionally a stitch tie is required. In some of the

earliest operations, omentum was sutured over the defect in the pylorus, but this is seldom done anymore.

After the pylorus is returned to the abdomen the wall is closed in layers.

The anesthetic of choice in this series has been open drop ether. Procaine infiltration anesthesia was formerly used but has been almost entirely abandoned during the past few years.

POSTOPERATIVE TREATMENT

Considerable controversy exists concerning the proper postoperative treatment of pyloric stenosis. Some authorities advocate immediate full formula feedings while others give nothing by mouth during the first 24 hours after operation.

Faber and Davis of Stanford gave 10 infants a teaspoonful of barium sulfate suspended in 1 ounce of water from 1 to 5 hours after the standard Fredet Rammstedt pyloromyotomy. Periodic examinations with fluoroscopy and x rays were made to determine the rate and extent of emptying of the stomach immediately following operation. They found that in the average case the evacuation of the barium from the stomach did not begin for over 8 hours and that evacuation was not complete for 24 hours. Basing their argument on these findings they do not believe that early and frequent administration of food and water during the immediate 24 hour postoperative period is desirable.

Our routine postoperative feeding schedule has been a compromise between these two extremes.

The patient is given $\frac{1}{2}$ dram of water 1 hour after operation and the water is increased by $\frac{1}{2}$ dram every 2 hours. Two hours after operation the patient is given $\frac{1}{2}$ dram of formula and this is given every 2 hours with an increase of $\frac{1}{2}$ dram for each feeding until the patient has received eight feedings of water and eight feedings of formula. The patient is not awakened during the night for feedings. On the second day $\frac{1}{2}$ ounce of formula is given every hour and the water is discontinued. On the third day 1 ounce of formula is given every 2 hours. On the fourth day 2 ounces of formula are given every 2 hours. On the fifth

day the normal feeding schedule is resumed.

If the patient persists in vomiting the feedings are reverted back to the last change.

In our series 23 per cent had a slight amount of postoperative vomiting not requiring a decrease in formula feedings, 5 per cent required changes in formula feedings and in 3 cases reoperation was necessary.

It was seldom necessary to give parenteral fluids after operation because of severe vomiting.

The skin sutures were usually removed on the seventh or eighth day and the patient was discharged on the ninth or tenth day.

TABLE I — COMPLICATIONS

	0 to 24 1 to 24	25 to 48 1 to 48	49 to 72 1 to 72	73 to 96 1 to 96	97 to 120 1 to 120	121 to 144 1 to 144	Total %
Accidental duodenal perforation			3	5	7	3	9
Wound infections	4						5
Dehiscence of wound after infection							6
Bronchopneumonia		3					4
Otitis media	3						5
Recurrentes			1				3
Hernia of wound							8
Hemorrhage							4

*One died

†Three died

Accidental perforation of the mucosa. The most frequent complication in our series, and the one most commonly warned against in the literature is accidental perforation of the duodenal mucosa. This complication occurred 21 times in our series of cases. Ladd (12) reported 23 perforations in his series of 1000 cases.

It should be routine for every operator to test for possible perforation by squeezing the stomach and duodenum together and watching for the escape of gas bubbles.

Wound infection. Wound infection was the second most common complication occurring in 12 cases. Four of these resulted in dehiscence of the incision and 1 of the 4 died of a resulting peritonitis.

Upper respiratory infection. was a complication in 12 cases. Half of these patients developed otitis media and the remaining suffered with nasopharyngitis.

TABLE II—OPERATIVE MORTALITY—232 PATIENTS OPERATED UPON WITH 9 DEATHS—3.8 PER CENT MORTALITY

935—Peritonitis (recurrence reoperated upon) (autopsy)
93—Peritonitis (recurrence reoperated upon) (autopsy)
93—Bronchopneumonia (autopsy)
929—Inanition—dehydration (autopsy)
938—Bronchopneumonia (autopsy)
928—Bronchopneumonia (autopsy)
937—Peritonitis (sound dehiscence) (autopsy)
920—Peritonitis (autopsy)
935—Bronchopneumonia (no autopsy)

TABLE III—MEDICALLY TREATED MORTALITY—15 PATIENTS TREATED MEDICALLY WITH 7 DEATHS—46.6 PER CENT MORTALITY

937—Pyloric obstruction—inanition
934—Pyloric obstruction—inanition
931—Pyloric obstruction—bronchopneumonia
929—Pyloric obstruction—malnutrition
927—Pyloric obstruction—bronchopneumonia
937—Pyloric obstruction—bronchopneumonia
926—Pyloric obstruction—malnutrition
(All are proved by autopsy)

Bronchopneumonia Bronchopneumonia was a complication in 7 cases. Four of these in infants died.

Postoperative vomiting Severe vomiting continued postoperatively in 12 cases and had to be treated with atropine. In 3 of these a diagnosis of recurrence was made and the infants were operated upon a second time to separate the muscle fibers which had been incompletely separated during the first operation. Two of the 3 died of peritonitis. The duodenum was accidentally perforated in the remaining case during the second operation but the accident was noted and the defect was closed with a mattress suture.

Recurrences There were 5 cases of recurrence in our series. Three of these received both their first and second operation here. The 2 remaining were operated upon elsewhere the first time and came to Milwaukee Children's Hospital for their second operation. It is possible that some of our patients were reoperated upon elsewhere because of recurrences but no such case has been brought to our attention.

Diarrhea Severe diarrhea complicated 4 cases resulting in prolonged hospital stay but not ending in any fatalities.

Hernia Postoperative abdominal hernias occurred in 2 cases. In both instances low right rectus incisions had been used.

Hemorrhage There was 1 case of intra-abdominal bleeding in which hemoglobin dropped to 3.5 grams. Transfusions were given and the bleeding stopped spontaneously. The remaining convalescence was uneventful.

MORTALITY—TABLES II AND III

Of the 247 patients treated for pyloric stenosis at Milwaukee Children's Hospital 16 died making a mortality rate of 6.4 per cent.

Two hundred and thirty two were treated surgically with 9 deaths giving an operative mortality rate of 3.8 per cent.

Of the 15 remaining patients treated medically 7 died with a mortality rate of 46.6 per cent.

There has been no death during the past 10 years and 172 patients have been operated on consecutively without a fatality.

This compares favorably with large series reported in the literature.

Ladd (13) reporting 1000 cases had an overall operative mortality rate of 4 per cent and had operated upon 225 consecutive patients without a death.

SUMMARY

1 The hospital records of 248 cases of pyloric stenosis were reviewed.

2 There were 9 instances in which more than one member of a family was affected and 7 instances in which one of a set of twins had the disease.

3 Biopsies of the pyloric tumor taken in 72 cases during operation and microscopic study revealed that the longitudinal as well as the circular smooth muscle fibers were involved.

4 Peristaltic waves were visible in 83 per cent of cases and tumors were palpable in 63 per cent of cases.

5 Roentgenologic examination too little used is a valuable diagnostic procedure since physical examination is not 100 per cent reliable.

6 Early diagnosis and adequate preoperative care are responsible for the reduction in mortality rate.

7 Routine blood transfusions at the time of operation make for a smoother convalescence and a reduction in postoperative complications.

8 There has been no death during the past 10 years and 172 consecutive patients have been operated on without a fatality

INFRARED PHOTOGRAPHIC STUDY OF THE SUPERFICIAL VEINS OF THE THORAX IN RELATION TO BREAST TUMORS

A Preliminary Report

LEO C. MASSOPUST Milwaukee Wisconsin

NORMAL patterns of the superficial veins in the living human body have been photographed by infrared photography and are recorded in the medical literature. In previous publications it has been shown also that infrared photography is of value in recording the changes in the superficial venous pattern caused by any condition which affects the circulation.

PURPOSE

This study is based on a survey of 100 cases of breast complaints entering the dispensary of the Marquette University School of Medicine from the Cancer Detection Center of the Medical Society of Milwaukee County. The object was to ascertain (1) whether a tumor within the breast would alter or disturb the pattern of the superficial veins of the thorax, (2) whether the infrared photograph might serve as an aid in determining whether the tumor was malignant or benign and (3) whether the infrared photographic method might be of any practical assistance in the diagnosis of cancer of the breast.

In approaching the problem it might be well to offer first of all some clue as to the nature of the types of venous patterns found in the normal human chest. For purposes of simplicity these venous patterns are referred to as infrared phlebograms and are classified into two types: longitudinal (Figs. 1 and 3) and transverse (Figs. 2 and 4). The *longitudinal* type radiates in a fan like pattern downward and laterally into the breasts from the point where the anterior jugular vein connects with the arch of the jugular vein (Fig. 1 A). This

pattern seems to be associated with the pendulous type of breast. The *transverse* type pattern radiates laterally in both directions from the pectoral venous plexus (Fig. 2 B) toward the axillary and costoxillary regions. The transverse type pattern is usually found in the normal youthful type of breast.

MATERIALS AND METHODS

Photographic materials, methods, and various applications of infrared photography have been discussed in previous publications. Any camera may be used. The image is focused with a Wratten No. 25 filter over the lens; this filter is then replaced with a Wratten No. 87 filter and the diaphragm is closed to the f 32 stop. The photograph is made on Eastman infrared sensitive film or plates. The back of the camera is tilted slightly upward to bring the plane of the film parallel with the plane formed by the protruding breasts. This is particularly necessary if the breasts are large.

The most convenient and efficient source of illumination for use with infrared sensitive emulsions is the incandescent tungsten filament lamp. In Figures 1 to 16 the patient is illuminated from each side by a vertical bank of five 100 watt lamps directed toward the chest and two 500 watt lamps directed toward the chest at an angle of about 45 degrees, 36 inches away from the patient. It is important to strive for flat illumination for very slight differences of light intensity are recorded with extreme contrast on the infrared sensitive emulsion. Movement is controlled by asking the patient to hold her breath. The exposure time is $\frac{1}{6}$ second. Infrared sensitive emulsions are loaded and processed in total darkness.

CASE REPORTS

Mrs. B. 40 years of age, weight 125 pounds, with one child 13 years old, entered clinic with no complaint but for checkup only. Infrared phlebogram revealed a symmetrical pattern of equal photographic density of the superficial veins in both mammary glands and pectoral regions, transverse type (Fig. 5).

Mrs. D. 35 years of age, weight 131 pounds, no children, had fibrocystic disease of both breasts. Infrared phlebogram revealed an undisturbed symmetrical pattern of the superficial veins in both mammary glands and pectoral regions. The veins just above the areola in each breast border on varicose, longitudinal type (Fig. 6).

Mrs. O. D. 37 years of age, weight 115 pounds, 2 children, had a tumor in right breast. Infrared phlebogram demonstrated an undisturbed symmetrical pattern of equal photographic density of the superficial veins in both mammary glands and pectoral regions. The pattern is revealed with unusual clarity, longitudinal type (Fig. 7). Pathologic examination revealed fibrocystic disease of the breast.

Mrs. J. 53 years of age, weight 138 pounds, 2 children, had a lump in the left breast. Infrared

phlebogram shows the superficial veins in the left mammary gland to be quite conspicuous, while those in the right breast are only faintly visible. There is also some engorgement of the veins which extend transversely across the left breast just above the nipple, longitudinal type (Fig. 8). Pathologic examination revealed adenocarcinoma, scirrhous type, grade III, with involvement of axillary nodes.

Mrs. B. 29 years of age, weight 168 pounds, 5 children, had a lump in right breast. Infrared phlebogram showed the superficial veins in both mammary glands and pectoral regions to be undisturbed, asymmetrical in pattern and of equal density, longitudinal type (Fig. 9). Pathologic examination revealed adenofibrosis of the breast with a solitary cyst.

Mrs. R. 50 years of age, weight 206 pounds, 3 children, had a painful lump in the left breast. Infrared phlebogram showed the venous pattern in the left mammary gland to be irregular in pattern and density, with engorgement of a vein in the pectoral plexus. A retracted area was present in the left breast just lateral to the nipple; this breast was distorted in shape. Slight changes in the shape of the

Fig. 5

Fig. 6

Fig. 7

Fig. 8

Fig. 9

Fig. 10

Fig. 11

breast are difficult to see upon visual inspection; the photograph, however, brings both breasts within the focus of the eyes, thus revealing these slight distortions quite clearly. The regularity of the venous pattern and density in the right breast contrasts greatly with those in the left (Fig. 11). Pathologic examination revealed scirrhous carcinoma with metastasis to lymph nodes—longitudinal type.

Mrs. C., 35 years of age, weight 126 pounds, 1 child, had a lump in the left breast. Infrared plethogram showed the superficial veins in both mammary glands and pectoral regions to be undisturbed and of equal distribution and density (Fig. 11). Pathologic examination revealed fibrocystic changes within a previous adenoma, with no evidence of malignancy. Transverse type.

Fig. 12

Fig. 13

Fig. 14

Fig. 15a.

Fig. 15b

Fig. 16a.

Fig. 16b.

Mrs H R. 55 years of age weight 151 pounds 10 children had an advanced carcinoma of the right mammary gland (Fig. 2)

Mrs K. 41 years of age weight 143 pounds 1 child had a painful lump in the left breast. Infrared phlebogram showed the superficial veins in the left breast more conspicuously than those in the right (Fig. 13). They are indefinite in outline and are somewhat enlarged. Note the wrinkle at the arrow. U lateral wrinkling just below the nipple has been observed in the photographs in a number of cases which proved to be malignant. It is probably caused by a lesion in the breast which produces a beginning retraction of the nipple. This slight wrinkling can be overlooked easily at visual inspection but is revealed very clearly in the photograph. Pathologic examination revealed a medullary carcinoma located deep in the left breast with some metastatic nodules present within the breast tissue.

Mrs B. 49 years of age weight 120 pounds no children, noticed a lump in the right breast a year ago which has increased in size. Infrared phlebogram shows the right breast to be distorted. There is a lump in the upper lateral quadrant and areas of unequal density below and above the nipple (Fig. 14). Note the three shallow wrinkles below the right nipple indicating greater retraction of the nipple than that seen in Figure 13. Pathologic examination revealed a scirrhous carcinoma with regional lymph gland metastasis.

Mrs V B. 35 years of age weight 116 pounds no children was operated upon 6 years previously for cyst in the right mammary gland posteriorly. A lump recurred slightly anterior to the old scar. There is drainage through the nipple with constant pain. Infrared phlebogram anterior view (Fig. 15a) shows that the superficial veins in the right mammary gland are more conspicuous than those in the left. The outline of a lump can be seen in the axillary region on the right side. In the lateral view (Fig. 15b) the patient's arm is raised over her head thus flattening the surface in the axillary region. Note the area of increased density indicated by the arrow just anterior to the scar of the previous operation. This area of density in the infrared photograph could not be seen upon inspection. There is a confluence of the veins toward this dark area. Pathologic examination revealed an adenocarcinoma, grade III without demonstrable axillary involvement.

This patient, a woman 63 years of age weight 51 pounds, with 1 child had a tumor mass with super-

ficial lesion in right mammary gland. Medullary type of carcinoma (Figs. 16a and 16b)

CONCLUSIONS

Of the 100 cases of breast complaints studied 65 were tumors. Following the study of about 75 cases of breast tumors, certain standards in the interpretation of the infrared phlebogram were established. In at least 6 patients brought in subsequently the phlebogram did not agree with the clinical diagnosis. In all of these cases, however the pathologic diagnosis confirmed the findings in the infrared phlebogram.

As a result of this limited study by infrared phlebogram the tentative conclusions are made

1 In some breast tumors the appearance and pattern of the superficial veins of the thorax are altered

2 The infrared photograph reveals information difficult to obtain upon unaided visual inspection and in some cases impossible to obtain in any way other than by an infrared phlebogram

3 Further study of many more benign and malignant tumors might indicate that the infrared phlebogram may serve as an additional adjunct in the detection and classification of tumors of the breast.

Realizing that the evaluation of the infrared phlebogram in the study of breast tumors can be established only by its general use, this laboratory is prepared to co-operate with others in the use of this simple procedure

REPAIR IN THE NORMAL AND HYPERACID STOMACH

An Experimental Study

PHILIP B PRICE, M.D., F.A.C.S Salt Lake City Utah

A RECENT experimental study of gastric digestion of living autogenous tissue provided unusual opportunities to observe the process of repair of wounds and incisions in the normal and hyperacid canine stomach. Those observations led to the present investigation.

A large number of healthy dogs were used. Discs of mucosa were excised from the gastric wall and incisions and anastomoses of various sorts were made. The animals were sacrificed at selected intervals to note the progress of repair.

About half of the animals received daily intramuscular injections of histamine in beeswax beginning 24 hours after operation. The fasting gastric contents of this group of dogs averaged 91 units of free acid and 124 units of total acid. The other group which received no histamine had on the average 22 units of free acid and 61 units of total acid.

No 60 cotton thread was used for the most part as suture material. Both cotton and fine catgut were tried in mucosa to-mucosa suturing.

REPAIR OF WOUNDS IN THE NORMAL STOMACH

In the postoperative stomach of an other wise normal dog repair proceeds in a characteristic manner. Figure 1 illustrates schematically the healing process after a disc of mucosa and submucosa has been excised. First there is proliferation of fibroblasts and granulation tissue in the base of the defect (Fig. 1B) and turning down of the mucosal margins. This latter effect is probably due to digestion of underlying supportive submucosa. In a later stage of repair the base is heaped up with granulation tissue which may be covered with

a thin slough of necrotic material. The wound is now smaller thanks to fibrous and muscular contraction and the extreme laxity of the submucosa (Fig. 1C). From the under margins of the crests of mucosa new epithelium extends in sheets across the defect. At length the crests of mucosa meet like the heads of two rams (Fig. 1D) and the base becomes completely epithelialized. When that has occurred digestion of tissue by gastric juice ceases and signs of inflammation subside.

Figure 2 is a photomicrograph of the margin of a healing wound after 4 days. The rounded crest of mucosa appears on the far left. There is a beginning of gland formation as well as active proliferation of epithelium which extends over the granulation tissue in the base of the wound. The muscularis mucosae is not seen in this view as it lags behind the advancing ram's head of mucosa.

If the original wound is large so that final healing is long delayed the advancing margin of mucous membrane may be edematous (Fig. 3). In this edematous stroma one may see newly formed capillaries and lymph channels.

Figure 4 shows an originally large wound now almost completely healed. Beneath the mucosal union the muscularis mucosae layers approach each other. Healing at length will be so perfect that it is hard to find the scar.

even on microscopic section. That is the normal process of healing.

REPAIR OF WOUNDS IN THE HYPERACID STOMACH

A very different picture is presented, however, when the gastric acidity is increased by

daily intramuscular injection of histamine in beeswax. There is no evidence of epithelial proliferation on the third day (Fig. 5); instead, there are obvious erosion and disintegration of both margin and base of the wound.

One day later there is an effort at proliferation deep in the projecting sulcus of the ram-

epithelium, but it is protected from gastric juice and is clean and healthy. Six days after operation the incision is completely epithelialized (Fig. 12) and is, to all intents and

purposes, healed. Grossly the incisions appear healed without inflammation.

In striking contrast is the healing of simple incisions in the strongly acid stomach. Fig.

ures 13 to 15 show the progressive deterioration which often occurs. There are ineffectual attempts at proliferation. Mucosal margins may become more widely separated day by day. Figure 16 shows a low power cross-section view of such an incision after 7 days. The line of suture is represented by a trough 7 millimeters in width. It is deep, grossly inflamed and filled with products of deterioration and necrosis. Figure 17 is a photomicrograph of one edge of the trough.

This difference between rapid repair in the normal and imperfect repair or failure to repair in the hyperacid canine stomach is observed also in gastrojejunal anastomoses though here the difference is somewhat less pronounced, probably because excess free acid is partly neutralized by alkaline intestinal contents. Figure 18 shows a gastrojejunal junction which in the presence of normal acidity is almost completely healed after 7 days. In contrast, a gastrojejunal suture in the presence of hyperacidity is shown in Figure 19. The anastomosis remains incompletely healed after 12 days; there is some extension of epithelium from both mucosal margins but the intervening area, partly necrotic, is a poor surface upon which to lay down sheets of new epithelium.

COMMENT

Additional studies were made which show that defects and incisions in the process of healing under normal conditions tend to regress when the dog is given histamine in quantities sufficient to produce large amounts of strongly acid chyme. Conversely unhealthy looking defects and incisions in the hyperacid stomach improve and proceed to heal rapidly when histamine is withdrawn.

It is recognized that hypoproteinemia interferes with healing in the gastrointestinal tract as elsewhere. In these acute experiments an attempt was made to eliminate that factor.

Obviously these effects produced in dogs under artificial experimental conditions should not be applied uncritically to clinical problems but do provoke speculations and suggest practical points for further investigation.

They help perhaps to explain why peptic ulcers persist or enlarge in the presence of excessive amounts of acid but tend to heal

when by one means or another the acidity of the stomach is reduced to or below normal.

They suggest that healing of gastric incisions and anastomoses might take place more normally and rapidly if operations on the hyperacid stomach were followed in selected cases by a few days of antacid medication. They also cast some doubt upon the value of the inner mucosa to-mucosa suture used in gastric surgery—provided hemostasis is secured otherwise.

SUMMARY

Gross and microscopic studies were made of operative defects and sutured incisions in the gastric wall of normal dogs and dogs receiving daily injections in histamine in beeswax.

In approximately 100 normal dogs no spontaneous ulcers were observed. Artificial defects in the gastric wall and lines of incision all showed relatively rapid healing characterized by minimal autodigestion, relatively mild inflammatory reaction, protective and reparative fibrosis, vigorous proliferation of gastric epithelium and early approximation of the mucosal margins.

In dogs with hyperacidity on the contrary spontaneous ulcers, artificial defects and sutured incisions all showed inflammation, necrosis and autodigestion. Fibrosis and granulation tissue were present, but gave the appearance of being unsuccessful barriers to a progressively destructive process. Epithelial regeneration was generally slight or absent and in many instances there was progressive undermining and destruction of marginal gastric mucosa. The severity of the erosive process was roughly proportional to the degree of acidity of samples of fasting gastric contents.

These two conditions of normal repair and of failure to repair in the presence of hyperacidity could be made to change from one to the other by giving or withdrawing histamine.

With due caution in applying experimental results to clinical problems it is suggested that these observations may help to explain the healing or persistence of peptic ulcers.

The question is raised whether operations upon the hyperacid stomach should not be followed by a few days of antacid therapy.

The value of the conventional mucosa to-mucosa suture in gastric surgery is doubtful.

PAINFUL HEELS IN CHILDREN

F. S. R. HUGHES M.D. M.S. F.R.C.S. Oxford England

PAINFUL heels in children are believed by many to be due commonly to an osteochondrosis of the epiphysis of the os calcis. There have been few reports on the histology of the condition. Hass in 1931 found gross disorganization of an epiphysis but Bergmann in 1926 and Frejka in 1927 both noted an absence of any abnormality. It has been suggested that the diagnosis depends on radiological signs but there is no uniformity of opinion as to what may be regarded as the typical x-ray appearances (Table I).

The epiphysis, the epiphyseal line, and the neighboring metaphysis have all been described as showing abnormal roentgenological features. Since it is on the recognition of these latter that the condition is classified as an osteochondrosis or epiphysitis, a large series of roentgenograms were first studied in order to establish the variations in this region in normal children.

THE EPIPHYSIS

Ossification begins in the epiphysis between the 6th and 8th years at multiple centers just below the middle of the posterior aspect of the os calcis. Extension takes place inferiorly superiorly and posteriorly and by the 9th year the epiphysis appears roentgenologically as a cap covering the lower two-thirds of the posterior aspect of the os calcis. During the 10th to the 12th years the remainder of the epiphyseal cartilage ossifies the upper one-third remains as a very thin plate of bone and like the most inferior portion of the epiphysis frequently begins from a separate center. By the 14th year therefore, the epiphysis is roughly C-shaped and extends from the posterior and superior corner of the metaphysis to the posterior part of the plantar surface.

The epiphysis is usually denser than the body of the os calcis; segmentation of the os-

ifying area into two or more segments is not uncommon. The edge of the epiphyseal ossification may be well defined or may be irregular and fluffy. The bone trabeculae run parallel to the surface and are usually but not always well marked.

THE EPIPHYSEAL LINE

During the 9th year the lower lateral edges of the epiphyseal ossification curve forward; this expansion considerably alters the roentgenological appearances because it obscures in this part the clear radiotranslucent line between the epiphysis and the metaphysis. Both the medial and lateral edges of the ossifying plaque can be seen frequently on either side of the posterior edge of the metaphysis of the os calcis. The epiphyseal line is finally entirely obliterated at approximately the 15th to 16th years.

THE METAPHYSIS

Trabeculae radiating posteriorly and inferiorly from the posterior subastragaloid joint are grouped into a slightly dense band passing to the cortex of the posterior surface and another passing to the posterior and inferior angle. Other trabeculae sweeping posteroinferiorly from near the anterior end of the

plantar surface of the os calcis intersect these former. The posterior surface of the os calcis becomes roughened and the previous sharp line on the roentgenogram is replaced by irregular ridges. These irregularities of the posterior end of the metaphysis together with the overlapping by the edges of the epiphyseal ossification and the arrangement of the bony

PAINFUL HEELS IN CHILDREN

F. S. R. HUGHES M.D. M.S., F.R.C.S. Oxford, England

PAINFUL heels in children are believed by many to be due commonly to an osteochondrosis of the epiphysis of the os calcis. There have been few reports on the histology of the condition. Hass in 1931 found gross disorganization of an epiphysis but Bergmann in 1926 and Frejka in 1927 both noted an absence of any abnormality. It has been suggested that the diagnosis depends on radiological signs but there is no uniformity of opinion as to what may be regarded as the typical x ray appearances (Table I).

The epiphysis, the epiphyseal line, and the neighboring metaphysis have all been described as showing abnormal roentgenological features. Since it is on the recognition of these latter that the condition is classified as an osteochondrosis or epiphysitis, a large series of roentgenograms were first studied in order to establish the variations in this region in normal children.

THE EPIPHYSIS

Ossification begins in the epiphysis between the 6th and 8th years at multiple centers just below the middle of the posterior aspect of the os calcis. Extension takes place inferiorly superiorly and posteriorly and by the 9th year the epiphysis appears roentgenologically as a cap covering the lower two-thirds of the posterior aspect of the os calcis. During the 10th to the 12th years the remainder of the epiphyseal cartilage ossifies the upper one third remains as a very thin plate of bone and like the most inferior portion of the epiphysis frequently begins from a separate center. In favor of this view is the absence of any other apparent cause for the painful heel and the undoubted fact that some films of normal feet display an epiphysis with regular edges. It has been claimed that the age period is characteristic but a painful heel is not uncommon at any age and frequently the underlying etiology is obscure.

There are certain facts, however, that do not support this classification. There is a lack of any histological proof of the disease. After a survey of our films and of those published by other authors it is impossible to agree that these differ in any way from a normal series of films. A follow-up examination revealed no residual anatomical abnormality in the heel clinically or roentgenologically despite the fact that pain sometimes persisted after fusion of the epiphysis and diaphysis.

The epiphysis may be involved in juxta epiphyseal affections of the os calcis (Figs. 43, 44, 45). But in such cases the primary meta-

trabeculae result in areas of apparent rarefaction and density of the metaphysis.

ROENTGENOLOGICAL APPEARANCES OF PAINFUL ADOLESCENT HEELS (Figs. 1 to 42)

Since 1939 23 children (17 boys and 6 girls) have sought treatment for painful heels (16 with bilateral symptoms) their ages varied from 6 to 14 years. Pain was intermittent but persistent usually precipitated by exercise and referred to the sides, the back or the inferior aspect of the heel. Apart from slight tenderness in 12 cases, there was a complete absence of physical signs. The roentgenograms of the heels of these patients presented a wide variety of appearances. The epiphysis sometimes seemed enlarged or flattened or irregular or segmented or sometimes presented a mottled or fluffy appearance the epiphyseal line was often cloudy and united the epiphysis to the irregular posterior surface of the body of

the os calcis. When studied in conjunction with the normal series it became clear that none of these x ray films presented pathological features.

DISCUSSION

In 1908 Haglund reported 2 rare but important surgical injuries brought on by violent exercise the first involved the tibial tuberosity and the second the epiphysis of the os calcis which he believed to be fractured or separated from the metaphysis. Sever in 1912 reported 5 cases of apophysitis of the os calcis and compared the condition with Osgood Schlatter's disease. A year later Edmond described irregular epiphyses in 2 boys each aged 13 years. Since then isolated cases and small series have been reported and most authors have followed Sever in classifying the condition as an osteochondrosis which implies an abnormality of the developing epiphysis.

Fig. 45. J. D., male, 13 years old, painful swollen heel for 6 weeks followed by sinus formation. Tuberculosis of os calcis.

physal lesion can be seen and roentgenologically the epiphyseal damage is restricted to a localized rarefaction and partial avascular necrosis. These appearances are not comparable with those found in painful adolescent heels.

This investigation leads to the conclusion that there is no proof that osteochondrosis or epiphysitis (or apophysitis) is the underlying cause of these adolescent painful heels.

SUMMARY

1. A description has been given of the normal variation in the appearances of the ossifying epiphysis of the os calcis.

The clinical and radiological features of 39 painful heels in children between the ages of 6 and 14 years old are described.

3. It is concluded that there is insufficient proof that osteochondrosis is ever the underlying cause of adolescent painful heels.

ACUTE PANCREATITIS

A Statistical Review of 307 Established Cases of Acute Pancreatitis

JOHN R. PAXTON M.D. F.A.C.S. and J. HOWARD PAYNE, M.D. Los Angeles, California

THIS study was undertaken with two objectives in mind: first, to improve our diagnostic accuracy by a proper classification, correlation and understanding of the clinical picture; and second, to determine the proper treatment of acute pancreatitis. In addition, this report is justified as a statistical review as it represents a series of cases approximately four times larger than any group previously reported.

We shall neither discuss the etiology of acute pancreatitis nor review the literature.

MATERIAL

An established diagnosis of acute pancreatitis was made in 307 patients admitted to the Los Angeles County General Hospital during the period between January 1933 and January 1946. One hundred fifty-nine cases of the 307 were diagnosed by definite elevation of the blood amylase or urinary diastase; 103 cases were diagnosed at surgery; and 45 were either diagnosed or the diagnosis substantiated at the autopsy table.

CLINICAL PICTURE

Acute pancreatitis may affect all age groups. The youngest in this series was an 11-year-old girl; the oldest, an 86-year-old man. The average male was 41; the average female was 49. The majority of the patients were in the third decade of life.

Acute pancreatitis was more common in the women than in the men. There were 138 males and 169 females.

It has long been our clinical impression that this disease is more prevalent during warm weather. There was a higher incidence of acute pancreatitis during the hot summer months.

The initial pain began immediately after the ingestion of a heavy meal in 76 instances

(25%) a positive point in the history which can be of real diagnostic value. Repeated experiments have shown that pancreatic necrosis is more readily produced soon after the ingestion of a heavy meal—presumably when the pancreas is active producing digestive substances.

An unusually large percentage of these patients had previous similar—but less severe—attacks. These episodes were generally mild and of short duration, subsiding within 24 to 48 hours. There is universal agreement that these episodes represent a mild form of the disease and are commonly referred to as edematous pancreatitis or acute interstitial pancreatitis. The patient, however, may refer to them as indigestion, gastritis, or dyspepsia. It is not uncommon for a fatal attack to be preceded by several mild attacks. A past history typical of acute pancreatitis was elicited in 43 per cent of our patients. An additional 18 per cent had had some previous gastrointestinal difficulty suggesting the mild form of the disease. Therefore, 61 per cent of the 307 patients probably had had previous attacks.

Only recently has the rôle of alcoholism in the pathogenesis of acute pancreatitis received any attention. Fifty-five patients (18%) were admitted intoxicated or were recuperating from a recent alcoholic bout. We are certain that had more of the alcoholics been studied for acute pancreatitis, a greater number would have been included in this report.

SYMPTOMS

TABLE I—SYMPTOMS

	Number of cases	Per cent
Pain	290	94.5
Nausea	291	94.6
Vomiting	158	51.0

The 3 predominating symptoms in the acute phase of the disease are (1) pain, (2) nausea, and (3) vomiting. Of the 307 patients, 290 had abdominal pain. Sixteen were admitted

From the Department of Surgery of the University of Southern California School of Medicine and the Los Angeles County General Hospital. Presented to the sectional meeting of the American College of Surgeons at Los Angeles, California, April 8, 1946.

This investigation leads to the conclusion that there is no proof that osteochondrosis or epiphysitis (or apophysitis) is the underlying cause of these adolescent painful heels.

SUMMARY

A description has been given of the normal variation in the appearances of the ossifying epiphysis of the os calcis.

The clinical and radiological features of 39 painful heels in children between the ages of 6 and 14 years old are described.

It is concluded that there is insufficient proof that osteochondrosis is ever the underlying cause of adolescent painful heels.

ACUTE PANCREATITIS

A Statistical Review of 307 Established Cases of Acute Pancreatitis

JOHN R PAXTON M D I A C S and J HOWARD PAYNE, M D Los Angeles, California

THIS study was undertaken with two objectives in mind first to improve our diagnostic accuracy by a proper classification correlation and understanding of the clinical picture and second to determine the proper treatment of acute pancreatitis. In addition this report is justified as a statistical review as it represents a series of cases approximately four times larger than any group previously reported.

We shall neither discuss the etiology of acute pancreatitis nor review the literature.

MATERIAL

An established diagnosis of acute pancreatitis was made in 307 patients admitted to the Los Angeles County General Hospital during the period between January 1933 and January 1946. One hundred fifty nine cases of the 307 were diagnosed by definite elevation of the blood amylase or urinary diastase 103 cases were diagnosed at surgery and 45 were either diagnosed or the diagnosis substantiated at the autopsy table.

CLINICAL PICTURE

Acute pancreatitis may affect all age groups. The youngest in this series was an 11 year old girl the oldest an 86 year old man. The average male was 41 the average female was 49. The majority of the patients were in the third decade of life.

Acute pancreatitis was more common in the women than in the men. There were 138 males and 169 females.

It has long been our clinical impression that this disease is more prevalent during warm weather. There was a higher incidence of acute pancreatitis during the hot summer months.

The initial pain began immediately after the ingestion of a heavy meal in 76 instances.

From the Department of Surgery of the University of Southern California School of Medicine and the Los Angeles County General Hospital. Presented to the sectional meeting of the American College of Surgeons at Los Angeles, California, April 8, 1946.

(25%) a positive point in the history which can be of real diagnostic value. Repeated experiments have shown that pancreatic necrosis is more readily produced soon after the ingestion of a heavy meal—presumably when the pancreas is active producing digestive substances.

An unusually large percentage of these patients had previous similar—but less severe—attacks. These episodes were generally mild and of short duration subsiding within 24 to 48 hours. There is universal agreement that these episodes represent a mild form of the disease and are commonly referred to as edematous pancreatitis or acute interstitial pancreatitis. The patient, however may refer to them as indigestion, gastritis, or dyspepsia. It is not uncommon for a fatal attack to be preceded by several mild attacks. A past history typical of acute pancreatitis was elicited in 43 per cent of our patients. An additional 18 per cent had had some previous gastrointestinal difficulty suggesting the mild form of the disease. Therefore 61 per cent of the 307 patients probably had had previous attacks.

Only recently has the rôle of alcoholism in the pathogenesis of acute pancreatitis received any attention. Fifty five patients (18%) were admitted intoxicated or were recuperating from a recent alcoholic bout. We are certain that had more of the alcoholics been studied for acute pancreatitis a greater number would have been included in this report.

SYMPTOMS

TABLE 1 — SYMPTOMS

	Number of cases	Per cent
Pain	290	94.5
Nausea	291	94.6
Vomiting	258	84.0

The 3 predominating symptoms in the acute phase of the disease are (1) pain (2) nausea and (3) vomiting. Of the 307 patients, 290 had abdominal pain. Sixteen were admitted

in coma with no history. One patient with epidemic parotitis had no abdominal pain. This patient developed persistent nausea and vomiting during the acute phase of mumps. Both the blood amylase and urinary diastase were significantly elevated. A clinical diagnosis was made of mild acute pancreatitis secondary to the parotitis.

The pain was epigastric in location in 114 cases, epigastric radiating to the back in 122 cases, epigastric in origin becoming generalized, in 38 cases. However of this group with upper abdominal pain, there were 39 cases in which the pain originated in the right upper quadrant and radiated through to the back, simulating acute cholecystitis. On examination unilateral or bilateral flank tenderness was found. Flank pain and tenderness is of definite diagnostic significance in acute pancreatitis.

Seventeen patients presented an unusual pattern for acute pancreatitis in that the pain began suprapubically and radiated to one or both flanks. This distribution of pain in any acute condition within the abdomen is not particularly common. When this syndrome presents itself the blood amylase and urinary diastase should always be determined.

Eighty-four per cent of the 307 patients had nausea and vomiting. Reflex vomiting appears early and is generally persistent. Later in the course of the disease the vomiting is variable dependent upon the amount of ileus present or the degree of duodenal obstruction from the enlarging pancreas. The absence of nausea and vomiting was not sufficiently characteristic in any syndrome to have statistical significance.

From a clinical standpoint the disease usually falls into one of five groups. In *Group 1* is seen the standard textbook description of acute pancreatitis—an elderly obese stolid individual who has eaten a large meal preceded by several highballs. A few hours later he is seized with excruciating upper abdominal pain followed immediately by nausea and profuse vomiting. Generally he is in profound shock with cyanotic mottled skin and diffuse abdominal rigidity and tenderness. Peristalsis is infrequent or absent. Later he may have ecchymosis of the flanks or the umbilicus. Death

ensues within 24 to 36 hours with a terminal hyperpyrexia (105 to 106 degrees F). The patient who simulates acute coronary occlusion is included in this group. Four patients had substernal pain with radiation to the epigastrium. In 2 other cases the pain was localized in the precordium. These 6 patients were admitted with a diagnosis of acute coronary occlusion. In 3 of these fat necrosis was observed in the left pleura and the pericardium at the post mortem.

Group 2 simulates acute cholecystitis. The onset is usually sudden with moderately severe epigastric or right upper quadrant pain. The pain often radiates through to the back and is followed at once by nausea and persistent vomiting. In the past, the patient has experienced similar seizures, but jaundice is not often reported. Thirty-nine patients in this series gave such a history. On admission in 33 of the 39 an erroneous diagnosis of acute cholecystitis was made.

Group 3 imitates mechanical small intestinal obstruction. These patients are seemingly so characteristic that a diagnosis of mechanical small intestinal obstruction is made in the admitting room. However there is no apparent etiology—such as hernia or abdominal scar—for the obstruction. Any patient who appears to have an intestinal obstruction without obvious etiology should have a blood and urinary diastatic activity determined before surgery is contemplated. In 26 patients in this series first a diagnosis of intestinal obstruction was made—later of acute pancreatitis.

Group 4 resembles acute alcoholism with acute gastritis. Included in this category are those patients that are thought to have perforated a peptic ulcer. Patients in this group often are admitted either intoxicated or they give a history of having been on a recent, prolonged, alcoholic spree. Subsequently they develop abdominal pain, nausea, and vomiting. However these symptoms may be minimal. The slight degree of abdominal rigidity often leads to the mistaken diagnosis of a slow leaking peptic ulcer. The known high frequency of acute pancreatitis during or following acute alcoholism compels us to determine the diastatic activity of the blood and urine as a routine measure.

Group 5 comprises those patients who on admission have a mass either in the epigastrium or the left upper quadrant. Approximately 3 to 4 weeks prior to admission they had acute pancreatitis. A pancreatic abscess, a pseudocyst or inflammatory exudate remained as a tender mass. Their initial symptoms may fall into any of the four groups described.

ASSOCIATED SYMPTOMS

TABLE II.—ASSOCIATED SYMPTOMS

	Number of cases	Per cent
Diarrhea	22	71
Bloody diarrhea	4	45
Hematemesis	10	31
Hypertension	60	95

Gastrointestinal hemorrhage. An extremely interesting symptom which may confuse the clinical diagnosis is gastrointestinal hemorrhage. Twenty four of our patients had massive gastrointestinal hemorrhage—14 times as a bloody diarrhea and 10 times as a bloody vomitus. At the postmortem examination numerous areas of hemorrhagic ulceration were observed in the mucosa of the stomach, small intestine and colon. After a cursory examination of the voluminous literature on pancreatitis we have not found any reference to these hemorrhagic areas of ulceration. Further study is now in progress to establish the cause and exact nature of these hemorrhagic areas and will be reported at a later date.

It has been demonstrated that the tryptic action of the pancreatic enzymes can produce vascular necrosis and hemorrhage in all tissues of the body. This may be the cause of the ulceration (Fig 1).

Diarrhea. Diarrhea may be a misleading symptom in the differential diagnosis of acute pancreatitis. It was present in 22 of our 307 cases. The diarrhea is caused by the initial increase in peristaltic movements produced by the irritation of the autonomic nerve supply to the intestine. Probably the absence of pancreatic enzymes in the intestine is a contributing factor. Constipation however is more common than diarrhea.

Clinical hypertension. Twenty per cent had clinical hypertension. It is significant that the

Fig. 1. Segment of ileum showing hemorrhagic ulceration of the mucosa.

average age of this group of patients (41 years for males—49 years for females) is not in the decade when hypertension would be expected. This observation varies from the widespread belief that profound shock is generally present. As can be seen from Table III, only 11.7 per cent were in shock. Two hundred thirty-seven cases (78%) had no clinical evidence of shock.

TABLE III.—DEGREE OF SHOCK

	Number of cases	Per cent
None	237	78.0
Moderate	19	6.2
Severe	36	11.7

The degree of shock principally depends on the pathology present. None will deny the presence of irreversible hypotension in the patient with widespread destruction of the pancreas. In the early stages, this reduction of blood pressure represents a neurovascular reaction excited by pain and tissue destruction. Later it merges gradually into secondary shock without an interval of partial recovery and precedes death in a state of severe peripheral vascular collapse. The state of peripheral vascular collapse is the probable explanation of the peculiar cyanosis exhibited by the patient. This is not to be confused with the brownish discoloration of the flanks (Grey Turner sign) or the slate blue color of the umbilicus (Cullen's sign). These are produced by an entirely different mechanism.

ASSOCIATED PATHOLOGY

Listed in Table IV are the various pathological lesions which were associated with these cases of acute pancreatitis.

TABLE IV — PATHOLOGY

	Number of cases	Per cent
Biliary tract disease	5	40.7
Alcoholism	35	18.0
Intestinal	3	
Appendicitis	3	
Intestinal	2	
Other	1	
Unrelated pathology	7	38.0

Each condition has been listed as probable etiological factors.

DIAGNOSIS

Table V lists the admitting diagnoses made in the series.

TABLE V — ADMITTING DIAGNOSIS

	Number of cases	Per cent
Pancreatitis	50	48.8
Cholecystitis	33	0.8
Perforated ulcer	50	6.3
Intestinal obstruction	26	8.5
Appendicitis		3.9
Gastrointestinal hemorrhage	8	.6
Alcoholism	7	3
Coronary occlusion	6	9
Miscellaneous	5	4.9

Acute pancreatitis may be suggested by the symptoms and findings but we must depend on the laboratory to establish the clinical diagnosis. The various laboratory aids in the diagnosis are (1) elevated blood amylase (2) elevated urinary diastase (3) depressed blood calcium (4) roentgenogram of the abdomen (5) changes in the electrocardiogram (6) elevated blood sugar (7) sugar in the urine.

DIASTATIC ACTIVITY

A definite elevation in the blood amylase usually occurs within the first 24 hours. Frequently a patient with acute pancreatitis has a normal serum amylase during the first 8 to 12 hours. This fact must be considered in correlating the laboratory findings with the stage of the disease. The blood amylase remains elevated 24 to 72 hours depending upon the severity of the disease. It usually returns to normal before the clinical subsidence of the disease. Here again the time element must be considered in establishing the presence of acute pancreatitis. The urinary diastase usually becomes elevated 12 to 24 hours later than the elevation of the blood amylase. It remains

elevated 24 hours or more longer than the elevated amylase. This however is not constant. The variability in the time of elevation of both the amylase and diastase is impressive. It is recommended that both the blood amylase and urinary diastase be done simultaneously in any suspected case of acute pancreatitis regardless of the elapse of time since the onset of the disease.

It must be remembered that the blood and urinary diastatic levels may be normal in cases that have widespread destruction of the pancreas. Apparently the gland is completely destroyed and the enzymes in the serum drop to normal or subnormal levels.

We use a rapid method of determination which was devised by Doctor Albert Chaney of the Los Angeles County General Hospital biochemical laboratory. It is a modification of the Somogyi method. This method has proved very satisfactory.

BLOOD CALCIUM

The blood calcium may become depressed due to the utilization of the ionizable calcium. Pancreatic lipase acts upon the fats splitting them into glycerol and free fatty acids. Calcium soaps are formed by a combination of the free fatty acids and the ionizable calcium. These calcium soaps have been observed many times at surgery and necropsy—also in roentgenograms of the abdomen. This depression of the calcium may be severe enough to produce clinical tetany. This has been reported by Doctors Edmondson and Berne and Doctors Edmondson and Fields.

ROENTGENOGRAM

In the later stage of the disease, the x ray picture of the abdomen frequently shows a segmental type of ileus which may involve the stomach, small intestine or colon. The transverse colon exhibits this selective segmental ileus more often than the rest of the bowel. One hundred twenty five of the 307 patients had emergency scout films of the abdomen—82 cases (68%) revealed a segmental type of ileus. This segmental distribution of gas is not pathognomonic of acute pancreatitis roentgenographically but it certainly suggests the diagnosis.

PAXTON PAYNE ACUTE PANCREATITIS

ELECTROCARDIOGRAM

A small group of patients with acute pancreatitis will exhibit changes in the electrocardiogram. Although these changes are non-specific, they are suggestive enough for the diagnosis to be considered. They are thought to be caused by a low calcium level. Positive correlation has been made between the blood calcium level and electrocardiographic changes. Ralph E. Homann has published a critical study of the electrocardiographic changes.

GLYCOSURIA AND HYPERGLYCEMIA

Some patients with acute pancreatitis spill sugar into their urine. They also have an increase in the blood sugar level. During the early years of this study, urinalyses were not done in all patients. Therefore, it would be a statistical fallacy to include part of the group giving the incidence of sugar. The elevated blood sugar level usually was high in the patients who had glycosuria. In 1 case, it was 1500 milligrams per 100 cubic centimeters of blood. In this group, there was no preceding history suggestive of diabetes. One must assume that the glycosuria is secondary to the acute pancreatitis. In the literature, there are several articles pointing out that diabetes may result from acute pancreatitis. This we have seen many times.

TREATMENT

The treatment of choice in uncomplicated acute pancreatitis is not surgical. Conservative treatment is recommended because of the results obtained. The objective of the treatment is to place the pancreas at rest. Pancreatic activity may be decreased by the following measures: (1) continuous gastrointestinal suction, (2) adequate parenteral fluids, (3) regular use of morphine sulfate, and (4) regular doses of atropine sulfate.

Continuous gastrointestinal suction is of extreme importance. By preventing the acid gastric secretions from entering the duodenum, the hormonal stimulation of the pancreas is reduced to a minimum. In addition, acute gastric dilatation is prevented and the ileus which develops is successfully treated.

The fluid and caloric requirements are met by administering 3000 to 4000 cubic centime-

ters of 5 per cent glucose solutions daily. No insulin is given unless it is necessary in the treatment of associated diabetes.

Regular injections of morphine sulfate (gr $\frac{1}{6}$ to gr $\frac{1}{4}$) are used to relieve the severe pain of the pancreatic necrosis and to place the gastrointestinal tract at rest. Remarkable relief from pain is obtained by a procaine block of the paravertebral sympathetic ganglia (T4-9). It is also known that the sympathetic supply excites external pancreatic secretion. A splanchnic block with single injection probably would be preferable.

Atropine sulfate is given in large doses (gr $\frac{1}{15}$ to gr $\frac{1}{100}$) every 3 to 4 hours. This effort is designed primarily not to relax the sphincter of Oddi but to suppress the vagus mechanism. Stimulation of the vagus produces a concentrated pancreatic juice rich in enzymes.

Reverse Trendelenburg position favors respiration without the hazard of obstructing the return venous flow.

One additional measure that may favorably alter the course of acute pancreatitis is the use of x-ray therapy. This is given during the acute phase of the disease. An analysis of our experience with this therapy is to be reported at a later date by Doctor Leo Levi of the Department of Radiology, Los Angeles County General Hospital.

Patients with acute pancreatitis on the treatment outlined may show rapid clinical improvement. Other than a slight elevation in temperature, the patients have no symptoms or findings of acute pancreatitis. Diastatic activity is within the normal range. If the gastrointestinal suction is discontinued and the oral feeding started, an exacerbation of the disease results. It is our policy to continue the intensive conservative treatment until the temperature has been normal for a minimum of 48 hours. The febrile response is an important guide in determining when treatment can safely be discontinued.

A review of the literature concerning the treatment of acute pancreatitis indicates a predominance of opinion in favor of immediate surgical interference. It has long been our clinical impression that the mortality in those patients with acute pancreatitis who are operated

upon—irrespective of the procedure performed—is definitely greater than the mortality in those that are not operated upon. The following report on the results substantiate our impression.

Table VI indicates the total number of cases as 307 with 102 deaths—a mortality of 33.3 per cent. Of the 307 patients, 103 were operated upon with 46 deaths—a mortality of 44.7 per cent. In the group that were not operated upon there were 204 patients with 56 deaths—a mortality of 27.5 per cent.

MORTALITY

TABLE VI—MORTALITY

	Number of cases	Deaths	Per cent
Operated upon	3	46	44.7
Not operated upon	204	56	27.5
Moribund	6	6	100
Not operated upon less moribund	88	40	3
Total	307	102	33.3

However of these 56 deaths in patients who were not operated upon 16 patients were admitted in *extremis*. Therefore they should not be classified in either category insofar as the effects of any specific therapy is concerned. If this moribund group of 16 cases is deducted from the 204 patients treated without surgery 188 cases remain with 40 deaths—a 21.3 per cent mortality.

In the group operated upon during the acute phase of the disease Table VII indicates the various types of operations performed, the number of cases, and the deaths. These data statistically have no significance except to point out that irrespective of the procedure the end results are poor.

TABLE VII—OPERATIONS

	Number of cases	Deaths	Per cent
Exploration	53	24	45.3
Cholecystectomy		9	42.8
Drainage of pancreas		5	30.0
Cholecystectomy	8	3	37.5
Cholecystectomy and pancreatic drainage	5		100.0
Cyst drained	1		100
Cholecystectomy and common duct drainage	5	3	60.0

A study that we have started which is far from complete but which we wish to mention at this time is an operative procedure designed to prevent recurrence. The surgery referred

to is section of the vagus nerves. Division of the vagus nerves will interrupt the two important stimuli to the pancreas. The hormonal stimuli will be reduced to a minimum by decreasing the acid secretion of the stomach. The direct stimulation to the pancreas will be diminished greatly. To our knowledge, only 2 patients have had vagus sections for this disease. One was done on our service at the Los Angeles County General Hospital, and the other in a private hospital by another member of our staff (Doctor A. C. Pattison). A detailed report of these cases will be published later.

SUMMARY AND CONCLUSIONS

1 We have presented a critical review of 307 established cases of acute pancreatitis in patients admitted to the Los Angeles County General Hospital during the past 13 years.

2 Five clinical syndromes of acute pancreatitis are described. Attention is directed to several important signs and symptoms. These are (a) massive gastrointestinal hemorrhage (b) diarrhea (c) segmental ileus seen on the emergency scout film (d) alcoholism, (e) the electrocardiographic changes (f) absence of shock, and (g) presence of hypertension.

3 Blood amylase and urinary diastase determinations if correlated with the stage of the disease are the most important aids in the diagnosis. It is recommended that both the blood amylase and urinary diastase be done simultaneously in any suspected case of acute pancreatitis.

4 The febrile response is the important guide in determining when treatment can safely be discontinued. Premature discontinuation of active therapy will result in reactivation of the disease.

5 There was an over-all mortality of 33.3 per cent. The patients that were operated upon as emergencies had a mortality of 44.7 per cent. In the group that was not operated upon, the mortality was 21.3 per cent indicating that conservative therapy is superior to any operative procedure during the active phase of acute pancreatitis. This we believe is equally true in either the acute edematous pancreatitis or the hemorrhagic variety.

Study of each patient included a careful inquiry into the nature of the injury the extent of the motor and sensory dysfunction the onset, character, and constancy of the pain, as well as factors which either caused exacerbation or amelioration of symptoms. Each patient was given a complete neurological examination and most of them underwent a careful evaluation of the vasomotor status. Skin temperature studies were carried out in the major oscillometric studies in some.

Sympathetic blocks were performed by the introduction of 0.5 per cent procaine with adrenalin into the paravertebral space between the first and second dorsals in the case of lesions of the upper extremity between the first and second lumbar in lesions of the lower extremity. The efficacy of the injection in blocking the sympathetic pathways was established by such observations as the presence of a Horner's syndrome, cessation of sweating and vasodilation. Sympathetic ganglionectomy for the lower extremities was accomplished through an anterior extraperitoneal approach under spinal anesthesia. The upper extremities were denervated by the posterior preganglionic operation of Smithwick performed under intratracheal anesthesia. There were no deaths and no serious complications. A single patient was treated by paravertebral alcohol block.

RESULT

Fifty-seven patients were treated by permanent sympathetic interruption. Twenty-one responded well to single or repeated procaine sympathetic blocks. Two patients noted gradual steady improvement following neurolysis with eventual relief of all symptoms. Two patients obtained relief of pain following excision of a neuroma and neurorrhaphy. In this regard it is of interest that 11 patients who subsequently obtained relief of pain from sympathetic procaine blocks had noted no relief after neurolysis and 3 had noted no relief after neurolysis and neurorrhaphy. Similarly 13 patients who were benefited greatly by sympathetic block had observed no change in pain following neurolysis nor had 4 others following neurolysis and neurorrhaphy. In 3 there was a spontaneous subsidence of symptoms. The outcome in 5 patients is unknown.

One of the 5 was subsequently treated by sympathectomy and 1 was apparently improving under a course of intermittent venous occlusion when last heard from.

THE EFFECT OF PROCAINE ANESTHESIA

One hundred and eighty-one sympathetic blocks were performed in 83 patients. Excluded are a number of blocks carried out upon some of the patients before they came under our care. Seven patients in the series received no sympathetic anesthesia. Two were patients in whom sympathectomy was felt advisable under any circumstances because of poor circulation in a limb in which there was a large subcutaneously ruptured aneurysm. In another patient sympathectomy was also felt advisable because of extensive nerve damage from aneurysmorrhaphy with ligation of the brachial artery. Two were patients who obtained relief following neurolysis or neurorrhaphy and two who were rapidly making a spontaneous recovery at the time of the original examination.

In 5 instances the injection was ineffectual in anesthetizing the sympathetic chain and in relieving pain. In each case other injections were effectual in blocking the sympathetic nerves and in relieving pain. In a few cases relief of pain was incomplete. In some of these the burning pain was relieved completely and the residual discomfort consisted of a persistence of other painful sensations such as tingling or aching. One patient noted very little alteration of pain. He will be referred to more fully later. In the other instances the entire pain was dramatically relieved. In all of medical practice no results are more sudden or spectacular. Before the injection the patient would be in agonizing pain guarding his injured extremity with zealous care reluctant to have it examined even after painstaking assurance that every effort would be taken to perform the examination in the gentlest manner. He would be hesitant to have the block itself carried out because he felt that his capacity to suffer prevented him from enduring any more discomfort even the prick of a needle which he had often heard from other sufferers might lead the way to cure. As soon as the injection

TABLE I.—DURATION OF RELIEF OF PAIN WITH REPEATED PROCAINE SYMPATHETIC BLOCKS IN THOSE PATIENTS SUBSEQUENTLY TREATED BY SYMPATHECTOMY WHO HAD MORE THAN ONE BLOCK BEFORE OPERATION

was completed his careworn face would assume an expression of extreme satisfaction, the beads of perspiration would disappear and he would settle back with a sigh of relief to enjoy his respite. Adequate examination which had before been difficult or impossible was now easily performed.

The duration of relief varied. In some instances it lasted only for the period of the anesthesia, while in others it lasted for hours, days or even permanently. In a few the exact duration of the relief of pain is not recorded. Seventy-eight blocks were followed by relief of pain for 2 hours or more. In the remainder the relief lasted only for the length of the sympathetic anesthesia, 1½ hours or less. It was a very striking finding that in some instances the duration of relief was the same after each block or grew progressively shorter (Table I). All patients who had such a response were treated by sympathectomy except for the occasional patient who appeared to be getting well spontaneously or was relieved by excision of a neuroma and suture. In some patients on the other hand each successive block was followed by a progressively longer period of relief (Table II). These patients in general tended to obtain permanent relief from such treatment. It was a striking finding that in the first group the initial injection tended to be prolonged beyond the period of sympathetic anesthesia. For example, of the 31 cases recorded in Table I in which multiple blocks were carried out before sympathectomy the original block gave relief of 1½ hours or less in 14 or 42.5 per cent while the same brief cessation of pain was noted in 21 of the remaining 23 patients (91.3 per cent) who had a single sympathetic anesthesia before sympathectomy. On the other hand, all of the 21 patients listed in Table II who obtained permanent relief from one or more procaine blocks were freed from pain for prolonged periods by the first injection except for 3 in whom it was felt the sympathetic anesthesia was incomplete. It is also evident from the data in Table I that when relief from the first injection was limited to the period of sympathetic anesthesia subsequent blocks generally gave no more prolonged respite from pain. When each successive block resulted in a shorter period of relief no permanent alleviation of pain was achieved by further injections (Table I). On the contrary those patients who were eventually rendered free of pain by procaine blocks generally noted progressively longer periods of freedom from pain following each successive injection.

TABLE II—DATA CONCERNING PATIENTS PERMANENTLY BENEFITED BY PROCAINE SYMPATHETIC BLOCKS

Case No.	Nerves injured	Degree of causalgia	Duration of causalgia in mos.	Duration of relief following sympathetic blocks (d)					Remarks
				1	nd	3rd	4th	5th	
	Radial	+++							
	Sciatic	+++	4	P					
3	Brachial plexus	++++	4	P*					Complete relief except for occasional slight dull ache in thumb
4	Sciatic	++++	5	P			P		
5	Sciatic	++	5	P					Very slight residual pain subsequently relieved by excision of neuroma and neurolysis
6	Sciatic	++	7	P					
7	Ulnar	++	9						
8	Sciatic	++++			P				
9	Sciatic	+++		MI	II	P			Each of sat two blocks resulted in lasting diminution of pain
10	Median radial, ulnar	++	35						Complete relief except for occasional mild twinges of pain
11	Tibial	++++							pain for 2 mos. occasional slight pain thereafter
12	Brachial plexus	++++	4D	P	SD	P			
13	Sciatic	++	4						
14	Median ulnar	++++	4	D					Only mild pain after sat block
15	Brachial plexus	++	7	P	S	SD	P		95% relief
16	Median, ulnar	++			S	4D	P		Complete relief except for occasional slight "hacking" sensation

20	Median, radial	+	45	P					
21	Sciatic	++++	45	P					
22	Sciatic	++	5	P*	4D	P			Complete relief 4 hrs., then returns of very mild pain. Gradual improvement in pain after 1 week
23	Sciatic	++	5	P					No pain for 9 days. 1 yr slight residual
24	Sciatic	++	5	P					Very light residual

(*) Symbols D—days, M—months, P—permanent. (†) Where no symbol is used the numeral designates hours.

Of the 83 patients in whom sympathetic anesthesia was induced one time or more 21 obtained permanent relief. The data concerning these patients are recorded in Table II. Ten were cases of causalgia of the upper extremity and 11 of the lower. The severity varied in 7 cases it was very severe in 4 moderate in 9 mild¹ and in 1 trivial. The pain was

In this communication the degree of causalgia has been classified in general as severe, moderate, or mild. Perhaps others would have designated these degrees of pain as excruciating, severe and moderate. We have used these terms in a comparative way, we do not mean to imply that these classified as "mild" had inconsequential pain but rather that the pain, distressing as it was, was mild in comparison with that presently suffered by those with more severe grades of causalgia.

of from 2 to 9 months duration or an average of 4 21 months. Ten required only 1 injection the remainder 2 3 4 or 5 injections. In some of the latter cases the pain was never as severe after the first injection. In 9 patients there was a persistence of very slight discomfort. In 1 of them all pain disappeared 12 weeks later and another lost his residual discomfort subsequently after excision of a neuroma and nerve repair. In all of the patients the residual pain was trivial in nature and often consisted only of intermittent mild paresthesias. Follow up observations extended over a number of months in all patients and

for more than a year in some. Altogether the results of sympathetic blocks in these 21 patients must be considered excellent.

RESULTS FOLLOWING SYMPATHECTOMY

Thirty four patients were treated by permanent interruption of the sympathetic pathways in the upper extremity 33 by operation one by alcoholic infiltration (Table III). In 10 cases the brachial plexus was injured in 10 the median radial and ulnar nerves, in 5 the median and ulnar in 4 the median in 3 the ulnar in 1 the radial, and in 1 the radial and ulnar. In 28 cases of the 34 there was injury to the median and in 29 to the ulnar nerve. In 3 cases the median paralysis was apparently complete and in 5 cases the ulnar paralysis appeared complete. In 11 instances there was associated thrombosis or posttraumatic operative ligation of the major arteries, in 8 involving the brachial in 1 each the subclavian the axillary and the radial and ulnar arteries in combination. In 2 additional patients the brachial artery had been ligated during operative treatment of a brachial aneurysm while in 2 others there was an aneurysm or arteriovenous fistula, one affecting the axillary artery and the other involving the brachial artery and vein. The causalgia was of extreme degree in 22 cases, of moderate severity in 7 and was mild in 4. The duration of pain at the time of operation ranged from 17 to 13 months an average of 47 months. In 25 patients the pain was completely relieved and in 6 others the residual discomfort was inconsequential. In these 31 patients (91 per cent) the result may be said to be excellent. In 2 the result was good in spite of incomplete relief of pain and in only 1 was the operation a failure. These last 3 cases will be presented more fully subsequently. All patients were followed for several months after operation and not a few for a year or more. None had any return of pain or increase in any residual discomfort.

Twenty three patients were treated by lumbar sympathetic ganglionectomy. The sciatic nerve was injured in 19 patients once in conjunction with the saphenous nerve. In 1 patient the saphenous nerve was injured, in 2 the peroneal and in 1 the tibial. Altogether

the tibial nerve was partially paralyzed in 15 patients, and apparently completely paralyzed in 3. There was apparent complete peroneal paralysis in 10 patients, partial paralysis in 2. The degree of pain was extreme in 3 patients, moderate in 8 and mild in 12. The duration of pain at the time of operation varied from 3 weeks to 14 months, an average of 5.28 months. The first second third and fourth lumbar ganglia were excised in 4 cases the first, second, and third in 5 the second and third in 11 and the second third, and fourth in 3. Relief of pain was complete in 11 patients and in an additional 4 patients an excellent result was obtained the residual discomfort being trivial. In 3 patients there was mild persistence of pain while 5 had relief only of about half their original pain. These 8 cases with only good or fair results will be discussed more fully subsequently. It is of interest that the result was excellent in 9 of the 11 cases with extreme or moderate pain and in 6 of the 12 cases with mild causalgia. The result was excellent in 7 of the 9 patients in whom the ganglionectomy included the first ganglion, and in 8 of the 14 in whom the highest ganglion resected was the second.

Of the 57 patients treated by operation (or alcohol injection) an excellent result was obtained in 46 or 81 per cent. In the remainder the relief of pain was satisfactory in all save 1 (Case 22 Table III) although suggestion may have played a part in the cure of 1 (Case 23 Table IV). Altogether the results were excellent in 37 of the 40 patients in whom the pain was moderate or extreme (92.5 per cent) and in 10 of the 17 in whom the pain was mild (58.8 per cent). In the 43 cases in which sympathetic denervation of the entire extremity was complete, an excellent result was obtained in 38 (88.4 per cent) and in 8 of 14 (57.1 per cent) in which the denervation was incomplete (cases of causalgia of the lower extremity in which the first lumbar ganglion was left intact). It would appear profitable to present in more detail the cases in which the result of operation was only good, fair or poor.

CASE 4 (Table III). This patient was a nurse anesthetist who had sustained a striking blow to her hand, forearm and arm in a struggle with a patient

TABLE III.—RESULTS OF DORSAL SYMPATHECTOMY IN CAUSALGIA OF UPPER EXTREMITY

Case No.	Nerves injured	Severity of causalgia	Duration of causalgia	Result of treatment
	Brachial plexus	+++++	4	Relief
	Median, radial, ulnar	+++	7	Relief
3	Median	+++	7	Relief
4	Ulnar	++	6	60% to 80% relief
5	Median	+++++	3	Relief
6	Median, radial, ulnar	+++++	6	Relief
7	Median, radial, ulnar	+++++	5	Relief
8	Brachial plexus	+++++	3	90% relief
9	Median, radial, ulnar	+++	4 1/2	Relief
10	Median, ulnar	+++++	7 1/2	Relief
11	Median, radial, ulnar	+++++	5	90% relief. Burning disappeared and aching off and on. Mild throbbing
12	Median, radial, ulnar	+++++	5	Relief
13	Median, ulnar	+++++	3	Relief
14	Median, ulnar	+++++	2	Relief
15	Median, radial, ulnar	+++++	7	Relief
16	Brachial plexus	+++++	3	Relief
17	Median, radial, ulnar	+++	3	Relief
18	Median, ulnar	+++++	4	25% relief. Burning disappeared. Less throbbing. Persistence of tingling and aching
19	Brachial plexus	+++++	2	Relief
20	Median, radial, ulnar	++	6	Relief
21	Median, radial, ulnar	++	5	Relief
22	Brachial plexus	+++++	4	5% relief
23	Radial, ulnar	+++++	4	Relief
24	Brachial plexus	+++++	4	Relief
25	Median, ulnar	+++++	5	Relief
26	Brachial plexus	+++++		Relief
27	Ulnar	+++	6	Relief
28	Radial	+++	4	Relief
29	Median	+++++		Relief
30	Ulnar	+++++	4	Relief
31	Median	++	6 1/2	90% relief
32	Brachial plexus	+++++	2 1/2	90% relief
33	Brachial plexus	++	3	90% relief. Occasional / intermittent shooting pains persisted
34	Brachial plexus	+++++		90% relief

*This patient was treated by alcoholic block of sympathetic chain.

during a difficult anesthetic induction. Thereafter progressively increasing signs of ulnar paralysis ensued. Six months after injury the ulnar nerve was explored at the elbow and found to be diffusely thinned and scarred. It was transplanted anteriorly. Little or no improvement in nerve function followed. Four months after the injury she had begun to have intense, constant burning pain in the hand largely

limited to the ulnar area. This was not influenced by the transplantation of the ulnar nerve. Six months after onset of pain a sympathetic block gave complete relief for 4 1/2 hours. Another block performed 3 days later gave similar relief for a slightly shorter period. Three days following this injection a preganglionic dorsal sympathectomy was performed. The patient was relatively comfortable

TABLE IV—RESULTS OF LUMBAR SYMPATHECTOMY IN CAUSALGIA OF LOWER EXTREMITY

Case No.	Nerves injured	Severity of causalgia	Duration of causalgia	Causalgia scored	Result of treatment
	Sciatic	++		3	Relief
	Saphenous	+++	5	3	Relief
	Sciatic	++++			75% relief. Burning disappeared. Slight mild tingling and aching
4	Sciatic	+++	6	1, 3	Relief
5	Sciatic	++			90% relief
6	Sciatic	+++	6	3	Relief
7	Sciatic	+++	6	3	Relief
8	Sciatic	++++		6	Relief
9	Sciatic	+++		6	Relief
	Sciatic	++		3	75% relief. Burning disappeared
	Sciatic	++	5	3	Some residual tingling
	Sciatic	++		3	90% relief
13	Sciatic	+++	5	1, 2, 4	Relief
14	Sciatic, Saphenous	++		1, 3	Relief
15	Sciatic	++		3, 4	90% relief
16	Sciatic	++		4, 5	90% relief
17	Sciatic	++		1, 3	90% relief
18	Peroneal	++		3	90% relief
19	Sciatic	+++	7.5	3, 4	90% relief
20	Tibial	++		3	90-95% relief
21	Sciatic	++++		3	90% relief
	Superficial peroneal	++		3	Relief
22	Sciatic	+++		3	90% relief. Residual pain at night for 3 weeks. Disappeared with reassurance

thereafter and required no narcotics or sedatives but occasionally had mild pain. She estimated that she had from 60 to 80 per cent relief. No explanation is offered for the continued mild pain.

CASE 18 (Table III). This patient sustained a shell fragment injury of his forearm. The median and ulnar nerves and questionably the radial, were badly damaged; there was a compound comminuted fracture of the radius and ulna; the radial artery was severed and had to be ligated; the ulnar artery was thrombosed. Two days after injury intense constant pain began. He complained of burning, tingling, pins and needles sensations, throbbing, and aching of the entire forearm and hand. Four months later a sympathetic block gave relief for 1 hour. A few days later dorsal sympathectomy was carried out. On questioning the patient he estimated that only about one-third of the pain was relieved. He no longer had any burning pain, however the throbbing was less and his residual discomfort consisted chiefly of tingling and aching. His circulation was improved and radial nerve function which had apparently been absent before was now found to be intact. He required no sedation and his appearance was one of comfort in contrast to one of abject misery before

operation. This case was atypical in the wide extent of the area in which pain was felt. The fractures were infected and ununited and part of the remaining pain was due perhaps to movement at the fracture sites. Altogether the result was good.

CASE 22 (Table III). The patient had sustained in a motorcycle accident avulsion of the trunks of his brachial plexus, thrombosis of the subclavian artery, acromioclavicular separation and fracture of the humerus. The circulation was precarious and he developed ischemic ulcers of the hand. Immediately after injury he complained of extreme burning, aching, mashing, and squeezing pain in his paralyzed forearm and hand and this continued unabated. Four months after injury an effectual sympathetic block gave relief of pain about the elbow and in the proximal forearm but none in the distal portions of the extremity. In spite of this poor response sympathectomy was performed the following day in the hope that it would provide relief, because there appeared no hope of saving the limb if the circulation could not be improved and because there was some question that the nerve paralysis might be ischemic in nature. The pain disappeared from the proximal third of the forearm but was as severe as ever distally.

Subsequent lysis of the plexus brought no relief nor did alcohol injection of the plexus. It is understood that the entire nenromatous plexus was subsequently excised but the eventual outcome is unknown to us. The patient was atypical in the wide extent of the area in which pain was felt. The result of the sympathectomy was a failure.

CASE 3 (Table IV) This patient was wounded in the thigh and popliteal space and sustained also a partial injury of the tibial component of the sciatic nerve. Severe constant, burning pain in the toes and sole of the foot began immediately. Five sympathetic injections were performed overseas and none altered the pain. It is not known whether sympathetic anesthesia was obtained. Four months after injury a sympathetic block resulted in cessation of pain for 1 hour. Three days later a second and third lumbar ganglionectomy was performed. The burning pain disappeared but he now complained of mild tingling and aching. In contrast to his preoperative state during which he was always in great pain and on the verge of tears, he now appeared happy and comfortable. Five weeks later a neurolysis was carried out with relief of the residual pain. It would appear that the tingling and aching sensations not complained of during the period of excruciating burning came to consciousness with relief from the burning. The result was considered good.

CASE 5 (Table IV) This patient noted immediate onset of mild burning and tingling in the sole and toes following a thigh injury in which the sciatic nerve was traumatized. There was evidence of a complete peroneal and partial tibial paralysis. Three sympathetic blocks performed 2½ months after injury gave relief on each occasion for about half an hour. Excision of a neuroma and partial neurotomy a few days later were without effect upon the pain. Six weeks afterward the second and third sympathetic ganglia were excised. The patient continued to complain of some pain but appeared more comfortable and slept well without narcotics, which had been required previously. That he was making the most of any residual pain was evidenced by these observations as well as by the fact that sterile subcutaneous injections of water now gave relief of pain although they had not done so before operation. He continued to improve. The result was considered good. In this case certain neuropsychiatric features may have been at play in the persistence of some complaints.

CASE 11 (Table IV) The patient had noted the onset of constant mild burning and tingling in the sole and toes 2 weeks following a wound of the thigh with injury of the sciatic nerve. Two sympathetic blocks performed a month later gave relief for 1½ hours on each occasion. A month afterward the second and third sympathetic ganglia were excised. There was no further burning but slight intermittent tingling persisted especially when the patient walked. This discomfort became progressively less. Nerve function improved steadily and when seen 3 months later he was free of all discomfort. The result was

considered good. This is an instance of relief of the major pain with persistence of some paresthesias.

CASE 12 (Table IV) Two weeks after an injury to the thigh in which the sciatic nerve was badly damaged, the patient began to have constant knife-like, tingling shock-like aching and burning pains in the ankle and sole of the foot. Though he complained bitterly observation suggested that his pain was mild in comparison with that of most of those with severe causalgia. Cold packs caused exacerbation of pain. A month after injury two sympathetic blocks gave relief for 1 hour on each occasion. A few days later an alcohol injection was made with production of only partial sympathetic anesthesia and with only slight reduction in pain. Sympathectomy was deferred until after neurolysis had been carried out and was then performed somewhat reluctantly because certain features of the case appeared atypical, especially the multiplicity of the types of pain and the lack of preponderance of burning. He had noted no improvement after lysis of the nerve which was badly scarred over such a long extent that excision and suture appeared impossible. Sweating observations after sympathectomy suggested that denervation of the lower extremity was complete. Most of the pain disappeared after sympathectomy and there was little left except a very annoying tingling which was felt especially in the peroneal distribution. He was able to take physiotherapy to walk with a brace and his edema disappeared. He slept poorly, however, complained a great deal and inquired about the feasibility of cordotomy. He was transferred to another hospital and when seen about 2 years later stated that the pain had disappeared after a femoral perianthelium sympathectomy had been performed. This would appear to be an atypical case in which some residual paresthesias were particularly disturbing to a patient with a low pain threshold. It is difficult to understand how perianthelium stripping could have been effective in a sympathetomized limb.

CASE 15 (Table IV) This patient had sustained a clinically complete sciatic injury from a wound of the thigh. He began immediately to have persistent mild burning stinging tingling throbbing and shooting pains throughout the entire foot. Four months after injury three sympathetic blocks were performed. There was relief of pain for 2, 1, and ¼ of an hour following these injections. A few days later a second, third, and fourth sympathetic ganglionectomy was carried out. Milder intermittent pains of the same character persisted although he felt considerably improved and was able to put weight on his foot and to sleep without sedation both impossible before operation. The result was felt to be good. One might speculate whether excision of the first lumbar ganglion as well would have resulted in complete cessation of pain.

CASE 16 (Table IV) The patient noted onset of constant, mild burning and tingling pains in the dorsum of the foot and in the toes immediately following a thigh injury in which he sustained a mild

damage to both components of the sciatic nerve. Nine months after injury he was given three sympathetic blocks, each of which resulted in cessation of pain for a 6 hour period. A month later the first second, and third sympathetic ganglia were removed. He estimated that half his pain was gone. The pain at rest largely disappeared but some mild burning and tingling was felt when he stood or walked. There was no longer any hyperesthesia. He continued to improve. The result was felt to be good.

CASE 20 (Table IV) After an unknown interval following wounds to his thigh and leg the patient developed mild burning pain in the foot. The injury had produced an aneurysm of the popliteal artery which had ruptured subcutaneously before admission. The tense swelling of the popliteal area caused such severe pain as to outweigh entirely the mild pain in the foot. Neurological changes consisted only of hypesthesia of the dorsum and sole of the foot with areas of marked hyperesthesia. Because of poor collateral circulation and the possibility of forced early operation, the second and third sympathetic ganglia were excised 3 months after injury. The pain decreased and the collateral circulation was improved. Three weeks after sympathectomy aneurysmorrhaphy was carried out. The result of sympathectomy in this patient was considered fair. The burning pain was less after ganglionectomy and was limited to the distal portions of the foot. The hyperesthesia largely disappeared.

CASE 23 (Table IV) The patient noted onset of burning pain in the sole of the foot a few days after a thigh injury which produced a large aneurysm of the profunda femoral artery. Signs of sciatic injury were limited to hyperesthesia of the plantar surface of the foot. Seven weeks after injury aneurysmorrhaphy was carried out. This effected no change in the pain. A few days later a sympathetic block was performed. This gave relief of pain for 3 hours. A second block the following day gave relief for 45 minutes. Three days later the second and third ganglia were excised. He complained of very mild pain off and on. Because certain features suggested an underlying hypochondriasis, suggestive persuasion was instituted. By the end of 3 months he was almost entirely free of pain. Certainly some relief can be attributed to sympathectomy but it is likely that suggestion played a rôle in the eventual excellent result.

DISCUSSION

As might be anticipated with a disorder so painful, so persistent and so debilitating as causalgia, almost every conceivable kind of medical physiotherapeutic, and surgical approach which offered any promise of cure has been tried. Some did no harm other than to allow the disorder to persist indefinitely by failing to relieve pain with resultant dysfunction of the extremity wearing down of morale

and not infrequently narcotic addiction. Others such as section and resuture of the injured nerve root section and cordotomy not only were often attended by failure but were unnecessarily destructive procedures. As experience has increased it has become evident that interruption of the sympathetic pathways constitutes the most reliable and safe method of treatment. Our present study confirms this concept. Although numerous successes following periarthral sympathectomy were reported some years ago direct attack upon the ganglionated sympathetic chain appears to produce more reliable results in causalgia as in other disorders amenable to sympathectomy.

In the present series of cases there were encountered only 4 instances of relief of pain following neurolysis or neurorrhaphy. In contrast 31 patients who subsequently noted cessation of pain following sympathetic blocks or sympathectomy had experienced no relief whatsoever after neurolysis or neurorrhaphy. This confirms the general unreliability of operative attack upon the injured nerve. In 15 patients who later had relief of pain from sympathectomy or sympathetic blocks, previous ligation and division of the injured artery had been performed without alteration of symptoms. Two other patients who had relief from sympathetic interruption had noted no alleviation following arterial stripping. These observations confirm the unquestionable superiority of operations upon or proximal injections of the ganglionated chain to periarthral sympathectomy. Only 3 patients were noted to undergo spontaneous subsidence of symptoms even though most of the patients were observed months and some a year or more after the onset of causalgia.

The results of sympathectomy were excellent. Over 80 per cent had complete lasting relief of pain or were left with only trivial discomfort. The result in the remainder was satisfactory in all save one the patients being sufficiently improved so that no further treatment was necessary. In addition to diminution of pain the local hyperesthesia disappeared entirely or in large part in all of them. In one patient it is not unlikely that encouragement and suggestion may have played a part

in the cure effected. The single case of complete failure was an atypical case with complete neuromatous involvement of the entire brachial plexus.

In those cases in which there was incomplete relief of pain several considerations must be taken into account. In the first place observations have been recently recorded (1,9) suggesting that it may be necessary in some instances to sympathectomize the site of injury as well as the area to which the pain is referred. Four cases have been recorded in which pain was relieved after excision of the first lumbar ganglion after incomplete relief following excision of the second and third ganglia, and 2 cases in which relief was obtained after excision of the twelfth thoracic or the eleventh and twelfth thoracic ganglia after incomplete relief had been obtained following excision of the lumbar chain. It is possible that inadequate sympathetic denervation may have been responsible for the incomplete relief in a few of our patients. Such a theory might be considered, for example, in Cases 3, 5, 15, 16 and 20 in Table IV in all of them there was persistence of mild pain and in all of them the first lumbar ganglion was left intact. Unfortunately such an explanation is hypothetical since subsequent procaine blocks or operative excision of the first ganglion were not performed because the residual discomfort was so inconsequential. Indeed in one of the cases (Case 5) it appeared fairly evident that certain neuropsychiatric factors were at play. This reasoning is not applicable in Cases 4 and 18 in Table III nor in Cases 12 and 16 in Table IV since in these patients the area of injury as well as the area of pain was fully denervated.

Without evoking any underlying hypochondriacal or other neuropsychiatric basis it seems likely that the persistence of mild paresthesias after relief of the principal burning pain is understandable as an increase in conscious appreciation of trivial discomfort to a level not felt formerly when more severe pain of other character was present. Paresthesias of this nature are commonly enough seen in injuries and diseases of nerves unassociated with causalgia. This explanation may serve for the incompleteness of relief in such cases as 18

Table III, and 3 and 11 Table IV. Finally recognizing full well the hazard of implying that failure of complete cure from any procedure is due to attendant neuropsychiatric factors, we feel that such factors do occasionally contribute to persistence of pain. This appeared to be true in Cases 5, 12, and 23. Indeed, 2 of these 3 patients continued to improve with reassurance, while the third obtained relief of residual discomfort from perianal stripping in an already sympathectomized extremity.

Though permanent relief of pain in causalgia from sympathetic procaine blocks has been reported some observers are in doubt that such cures can be effected in true causalgia. In 5 recent papers (1, 2, 3, 6, 9) in which a total of approximately 200 sympathectomies are reported, one author did not mention cures following sympathetic blocks alone, two noted cures in a few patients but stated that repeated blocks generally produced no permanent effect, another stated that repeated blocks were ineffectual in providing complete permanent relief, while the fifth observed prompt or delayed relief of pain of sufficient degree to make unnecessary other treatment in 45 of 91 patients. In our experience single or repeated procaine blocks effected a very satisfactory alleviation of symptoms in 21 of 83 patients in whom one or more injections were made. Our studies confirm the findings we have observed in other vasomotor disorders that there is little likelihood of obtaining lasting improvement from any number of injections if the good response to the first is limited to the period of sympathetic anesthesia. Even more reliably a decrease in the duration of relief with successive blocks suggests that a permanent cure cannot be effected by procaine blocks alone. On the other hand, if the initial injection gives relief prolonged beyond the period of sympathetic anesthesia or if successive blocks result in increasing periods of relief one should be encouraged to try to effect a permanent cure by means of a series of procaine injections.

SUMMARY

1. Sympathectomy is a safe and generally reliable method of treatment in causalgia.

2 Failures are extremely rare and incomplete cures uncommon. It is suggested that incomplete relief may result from failure to denervate the site of injury, as well as the area to which pain is referred from persistence of paresthesias which are observed in cases of nerve injury without causalgia, and from perpetuation by some underlying neuropsychiatric factors.

3 Sympathetic procaine blocks are not infrequently effectual in relieving the pain of causalgia. There is little likelihood that repeated procaine blocks will bring about permanent relief if the first injection causes cessation of pain only for the duration of the anesthesia or if successive blocks give relief for decreasing periods of time. One should be encouraged to proceed with a course of procaine blocks if the initial injection gives relief

prolonged beyond the period of anesthesia or if successive blocks result in increasing periods of freedom from pain.

EVALUATION OF TREATMENT OF SLIPPING OF THE CAPITAL FEMORAL EPIPHYSIS

IGNACIO PONSETI M.D., and CHESTER K. BARTA, M.D., Iowa City Iowa

IN order to evaluate the treatment of the slipping of the upper femoral epiphysis during its various stages the histories and roentgenograms of 169 patients who had been seen at the University of Iowa Hospitals from 1932 to 1947 were reviewed. Seventy three patients were selected because of good clinical and roentgenographic follow up. Fifty four of these had unilateral and 19 had bilateral slipped epiphyses making a total of 92 hips. The average follow up time for this selected group was 2 years and 10 months.

The patients were classified into 5 groups as follows

1 Preslipping stage—5 patients 1 with bilateral preslipping

2 Acute slipping or fracture separation of upper femoral epiphysis—19 patients, 1 with bilateral acute slipping

3 Chronic slipping with minimal to moderate displacement—31 patients, 4 with bilateral chronic slipping

4 Chronic slipping with marked displacement—21 patients 5 with bilateral chronic slipping

5 Residual deformity of femoral head and neck due to old slipped epiphysis—4 patients 1 with old bilateral slipping

Seven patients with bilateral slipping of the femoral head had different types of slipping in their 2 hips and were included as patients with unilateral slipping in 2 different groups. Therefore they are listed twice in this group classification. Twelve patients had bilateral slipping of similar type and are listed only once.

The age of the patients at the onset of symptoms varied from 11 to 17 years in boys with an average of 14 1 years and from 10 to 14 years in girls with an average of 12 1 years. One boy with bilateral slipping was 20 years of age and 1 girl with unilateral slipping was

25 years of age when they first complained of hip pain. Both patients had deficiency of their pituitary growth factor and the closure of all the epiphyses was greatly delayed. The right hip was involved in 43 patients and the left hip was involved in 49 patients. Fifty six patients, or 76 7 per cent, were male and 17 patients, or 23 3 per cent were female.

The end results were graded as follows

1 Perfect result—normal or almost normal hip joint and femoral neck contours full range of motion and no limp or pain

2 Moderate distortion of the femoral neck restriction of internal rotation only and no limp or pain

3 Marked distortion of the femoral neck, no internal rotation motion and moderate limitation of other ranges of motion, no or mild limp on exertion, and no pain

4 Marked distortion of the femoral head and neck marked limitation of hip motion in all directions limp and pain

PRESLIPPING STAGE

Five patients 1 with bilateral hip symptoms belonged to this group. They usually complained of weakness of the leg and limped on exertion. Pain usually did not appear until a few weeks later and then it was present only when the patient stood or walked for long periods of time. This pain was localized in the hip or radiated into the adductor region of the thigh. One patient never complained of any pain.

On physical examination the most consistent finding was limitation of internal rotation motion. One patient had hip pain and limp but no limitation of motion. Another patient had marked limitation of active hip motion in all directions. Limitation of internal rotation appeared before any actual anatomical displacement had occurred. This limitation of motion could be due to spasm of the obturator internus and gemellus muscles, which are in

From the Department of Orthopedic Surgery, State University of Iowa Hospitals.

close proximity to the posterior capsule of the hip joint. Howarth found a certain degree of synovitis in the hip joint in all the patients with preslipping on whose hip an exploratory operation was performed.

The roentgenographic examination showed generalized bone atrophy of minor degree of the bicipelvis and the upper femur on the affected side. This generalized bone atrophy was present only in the patients who had limped or did not use the affected leg at least for a few weeks, and was interpreted by us as disuse atrophy. Widening irregularity and fuzziness of the upper femoral epiphyseal line were constant findings. No disalignment between the femoral head and neck could be detected either on the anteroposterior or on the lateral roentgenograms (Fig. 1).

Result of treatment of the preslipping stage

a. Two patients with unilateral preslipping were given crutches for only a few weeks. One patient had pain and moderate limp for 6 months but slipping of the epiphysis never occurred (result 1). The other patient sustained a fracture separation of the epiphysis 7 months after onset of symptoms. The femoral head did not die, but the joint space became very narrow 1 year after the acute slipping resulting in marked limitation of motion in this hip (result 4).

b. Two patients with unilateral preslipping and 1 patient with bilateral preslipping were treated by drilling and pinning. This was done by inserting two threaded Steinmann pins from the outer aspect of the upper femur through the femoral neck into the femoral head. One of these patients was a 20 year old boy who had had a suprascapular cyst which caused hypopituitarism and which delayed closure of all the epiphyses. The suprascapular cyst had been removed. The results obtained in these hips were excellent (result, 4 hips, 1) (Fig. 1 d e).

Comment. The preslipping stage represents a potential danger as was demonstrated by one of our patients who sustained an acute separation of the epiphysis 7 months after the onset of symptoms. When the syndrome of preslipping is diagnosed drilling and pinning of the affected upper femoral epiphysis should be done without delay.

ACUTE SLIPPING OR FRACTURE SEPARATION OF THE UPPER FEMORAL EPIPHYSIS

Nineteen patients, one with bilateral fracture separation of the upper femoral epiphysis, belonged to this group. The patients usually gave a history of mild weakness, limp or pain on exertion in the affected limb a few weeks or months duration before the acute slipping took place. The acute slipping was brought about by direct trauma to the greater trochanter or by a minor fall. In one patient the acute slipping took place while turning over in bed.

Immediately after the trauma the patient had very acute pain in the hip and was unable to move the leg. Weight bearing was impossible. Upon physical examination it was found that the leg was in complete outward rotation and any attempted motion of the leg was extremely painful. There was marked spasm of all hip muscles. The affected limb was from $\frac{1}{2}$ to 3 centimeters shorter than the normal one.

The acute slipping was followed by a period of 2 to 3 weeks of absolute weight bearing intolerance. The acute pain and muscle spasm decreased gradually during these weeks, and some degree of free hip motion reappeared. However the hip remained moderately painful and in outward rotation. Osteoarthritis of the hip joint developed within a few months, with flexion adduction, and external rotation contractures (Fig. 2).

Anteroposterior and lateral roentgenograms revealed the femoral neck to be completely separated from the femoral head and displaced forward and upward. The contours of the displaced femoral neck were sharply demarcated (Figs. 3, 4, and 5).

Result of treatment of the acute slipping stage.

a. Three patients with unilateral acute slipping were seen from 4 to 22 months after the acute episode. They had had no treatment. The femoral head had not died in any of these 3 hips. However marginal osteophytes, subchondral cysts, and narrow joint space were evident on the roentgenograms taken on admission (Fig. 2). All patients had pain and limp (results—3 hips, 4).

b. Eight patients with unilateral acute slipping seen from 1 to 21 days after the acute

Fig. 1. Preslipping stage in the left hip in a 12 year old boy. The patient had lumped on the left leg for 5 weeks, but had had no pain. The left lower had been in traction for 2 weeks prior to admission. On examination, the left hip was painless and freely movable, except for complete limitation of inward rotation. The right hip was normal. Drilling of the left upper femoral epiphysis followed by the insertion of one threaded Steinmann pin was performed in October 1943. The same procedure was done on the right, 1 year later because symptoms of preslipping developed in the right hip. The patient was last seen in May

1947 and both hips were found to be symptomless and had normal range of motion. a, Direct print of a roentgenogram shows generalized bone atrophy of the left pelvic bone and upper femur. The left upper femoral epiphyseal line is wide and fuzzy. b and c, Lateral roentgenograms demonstrate that slipping of the femoral head has not occurred, but the epiphyseal line is wider and more irregular in the left than in the right. d and e, Roentgenograms taken 2 1/4 years later. The epiphyseal plates are ossified. No slipping ever occurred between the femoral head and neck.

Fig. 2. Roentgenogram of the right hip of a 6-year-old boy taken $\frac{1}{2}$ years after acute fracture separation of the right upper femoral epiphysis. This was not reduced. A plaster hip spica was applied 1 month later. The patient had persistent pain in the right hip and had limited ab- and adduction of the hip joint. Range of hip motion was very limited. Production of osteophytes at the upper margin of the hip joint is seen. The femoral head did not become necrotic.

episode were treated by closed reduction followed by the application of a plaster hip spica. A closed reduction was also attempted in 1 patient seen 3 months after the trauma.

Complete reduction of the fracture separation was obtained in 2 patients, seen 2 and 3 weeks after the acute slipping. The entire femoral head became necrotic in both instances and it took from 2 to 3 years to become completely resubstituted by new bone. The femoral head flattened and the hip joint space became very irregular (results—1 hip 3, 1 hip 4).

Fig. 3. a, Roentgenogram of the left hip of a 7-year-old boy who sustained a fracture separation of upper femoral epiphysis in July, 1938. The leg was manipulated 3 weeks later but only an incomplete reduction was obtained. Plaster hip spica was applied. b, Four months after manipulation the femoral head appeared necrotic. An area of absorption of the dead bone is seen in the inferior medial aspect of the head. In April, 1939, drilling operation of the left femoral neck and head was performed. Roentgenogram taken 4 months after the drilling opera-

tion shows that the absorption of the necrotic bone was now taking place both from the inner and outer aspects of the femoral head. Evidently new blood vessels had penetrated through the drill holes into the femoral head. c, Roentgenogram taken 5 years after the fracture separation. The femoral head is seen to be flat and deformed and areas of dead bone are still visible in its center. The left hip was shown to be in marked flexion and adduction contracture and there was very limited range of motion present.

Partial reduction of the fracture separation was obtained in 4 patients seen from 1 to 21 days after the acute slipping. The femoral head became completely necrotic in 2 hips and partially necrotic in the remaining 2 (results—1 hip 2, 2 hips, 3, 1 hip 4) (Fig. 3).

No reduction was obtained in 2 patients seen 2 weeks and 3 months after the acute slipping. Necrosis did not appear in the femoral head of the first patient (result—3). Complete necrosis occurred in the latter patient (result—4).

c. Five patients with unilateral acute slipping seen 1 day to 2 weeks after the acute episode were treated by closed reduction, followed by drilling and pinning of the upper femoral epiphysis.

The reduction was performed in 4 patients under anesthesia by gradual traction and internal rotation and mild abduction of the affected leg on an orthopedic table. Abrupt maneuvers were not employed. When the anteroposterior and lateral roentgenograms showed complete reduction a small incision was made over the lateral aspect of the upper femoral shaft. A long drill was inserted several times through the femoral neck into the femoral head in order to perforate the epiphyseal line. Two to three threaded Steinmann pins were then inserted into the femoral neck and head to immobilize the reduced head. A plaster hip spica was applied for 4 to 6 weeks.

tion shows that the absorption of the necrotic bone was now taking place both from the inner and outer aspects of the femoral head. Evidently new blood vessels had penetrated through the drill holes into the femoral head. d, Roentgenogram taken 5 years after the fracture separation. The femoral head is seen to be flat and deformed and areas of dead bone are still visible in its center. The left hip was shown to be in marked flexion and adduction contracture and there was very limited range of motion present.

Fig 4 a, Roentgenogram of a 12 year old boy who had a fracture separation of the right upper femoral epiphysis. This was reduced 4 days later by progressive traction and inward rotation on the fracture table with the patient under anesthesia. After the reduction the femoral neck and head were drilled and two threaded Steinmann pins were inserted. b and c, Roentgenograms taken 3 months after reduction show that the fracture displacement had been

slightly overreduced. The bone of the femoral head shows areas of irregular density. d, Roentgenogram taken 7 months subsequently shows the femoral head of uniform density and solidly fused to the neck. The patient is symptomless.

Some areas of increased bone density in the femoral head were seen on the roentgenograms taken a few months after reduction in 3 of these hips. These areas disappeared promptly and no damage to the joint or change in contour of the femoral head occurred. The bone of the femoral head of the fourth patient was always of uniform density. A normal hip was the result in each of these 4 patients (result—4 hips 1) (Fig 4).

The fifth patient seen 1 day after the trauma was submitted to repeated Leadbetter maneuvers until a perfect reduction was obtained. The femoral neck and head were then drilled and pinned. The femoral head became necrotic and deformed and the joint surface was very irregular (result—1 hip 4).

d. An 11 year old girl was seen 2 months after the acute episode. The roentgenograms showed a viable femoral head. The hip was exposed by an anterior approach and the epiphyseal plate was drilled. An intertrochanteric osteotomy was performed under direct vision and the distal femoral fragment was displaced medially under the femoral head. The result was excellent (result—1 hip 1) (Fig 5).

A 12 year old girl was seen 4 weeks after the acute episode. The roentgenograms showed that the femoral head was viable. An open reduction of the fracture separation of the epiphysis was performed with a wedge resection of the femoral neck. The entire femoral head became necrotic. The end result was a deformed and painful hip joint (result—1 hip 4).

c. Two 15 year old boys were seen 7 weeks and 1 year, respectively after the acute episode. In the first patient the femoral head was found to be nonviable and was removed at the time of the operation. A fascial hip arthroplasty was performed implanting the femoral neck into the acetabulum. The second patient complained of pain and marked limitation of motion in the hip. A fascial arthroplasty was performed. The end results were not satisfactory because both patients had some hip pain, limp, and limitation of motion in the affected hip (result—2 hips 4).

Comment. It is obvious from these statistics that a successful reduction of the acute slipping of the upper femoral epiphysis can be obtained if the patient is seen during the first 2 weeks following the accident. The reduction

drilling and pinning. Very marked stiffening of the hip and narrowing of the hip joint space occurred a few months after surgery c and d, Described in text.

the blood supply to the femoral head. The statistics on the open reduction show a high percentage of necrosis of the femoral head which entails a poor result. Very good results may be obtained by the drilling of the epiphysis followed by an intertrochanteric osteotomy performed under direct vision through an anterior approach to the hip joint with medial displacement of the distal femoral fragment under the head.

CHRONIC SLIPPING WITH MINIMAL TO MODERATE DISPLACEMENT

Thirty-one patients, 4 with bilateral chronic slipping, belonged to this group. The clinical symptoms of these patients were quite similar to those observed in the preslipping stage. However, weakness of the leg, limp on exertion, and pain were usually of intermittent character. Periods of several weeks or months duration of complete freedom from symptoms were frequently seen, alternated with periods of pain. Apparently the slipping occurred by repeated displacements of small degree rather than by a continuous and slow process. Several patients of this group had no complaints.

The physical examination revealed marked limitation or absence of internal rotation in all the patients of this group. Some limitation of abduction was also noted in many of them.

The roentgenograms revealed findings similar to those seen in the preslipping stage. In addition, however, the femoral neck appeared widened and shortened and the shadow cast by the epiphyseal plate was very wide and irregular due mostly to anteversion of the femoral neck. The displacement of the femo-

ral head posteriorly over the neck can be first detected only in the lateral roentgenograms and later on in the anteroposterior views as well (Fig 7 a and b).

Results of treatment of the chronic slipping stage with minimal to moderate displacement

a Six boys with unilateral chronic slipping were seen from 5 months to 2 years after the onset of symptoms. They were given crutches and advised to practice limited weight bearing on the affected leg for a few weeks or months. The slipping did not progress in any of these patients and the end results were good (results—3 hips 1 3 hips 2).

b Eight patients with unilateral chronic slipping were seen 1 to 8 months after onset of symptoms. A plaster hip spica was applied from 3 to 8 months and no or limited weight bearing was allowed. No further slipping occurred in any of these patients. The epiphyseal plate became obliterated from 5 to 12 months after onset of treatment, and very good end results were obtained (results—5 hips 1 3 hips 2).

c Thirteen patients, 1 with bilateral chronic slipping, were seen 1 to 15 months after onset of symptoms. They were treated by drilling and pinning of the upper femoral epiphysis (6) as were the patients of the preslipping group. No attempts were made to reduce the displacement. Plaster cast immobilization was not used after the operation. The epiphyseal plate became obliterated from 4 to 12 months after treatment. The results were excellent (results—11 hips 1 2 hips 2).

A 14 year old girl seen 7 months after the onset of symptoms was treated in the same

manner. The roentgenograms revealed no increase of the femoral head but the joint space became very narrow within a few months after treatment and the hip motion practically disappeared. This condition will be discussed later (result—4) (Fig. 7).

d. A 17 year old boy seen 18 months after onset of symptoms was treated by drilling of the upper femoral epiphysis and intertrochanteric osteotomy. The osteotomy was done to correct an external rotation contracture and was performed through a lateral approach. The distal femoral fragment was not displaced under the femoral head. The result was not very satisfactory (result—1 hip 3).

e. A 13 year old girl, seen 10 months after onset of symptoms, was treated by drilling of the upper femoral epiphysis. No internal fixation was used. Four months later the roentgenograms showed the epiphysis to be closed and no further displacement had occurred (result—1 hip 3).

Comment. In the patients with chronic slipping of minimal to moderate degree good results were obtained by simple rest from weight bearing for a few months or by prolonged immobilization in plaster hip spica (5) or by drilling and pinning of the upper femoral epiphysis. However in the patients treated by rest or plaster cast immobilization an average of 9 months was required before the epiphyseal plate became obliterated. On the other hand in the group of patients treated by drilling and pinning the average time for epiphyseal closure was 6 months. Furthermore the fixation of the femoral head to the neck by pinning offers assurance against further slipping and against acute slipping. The patient may be allowed complete freedom of motion following the operation. Weight bearing on the affected leg can be started 1 month after surgery.

CHRONIC SLIPPING WITH MARKED DISPLACEMENT

Twenty-one patients five with bilateral chronic slipping belonged to this group. The clinical symptoms of these patients were similar to those seen in the chronic slipping with minimal to moderate displacement although

the limitation of internal rotation and abduction of the hip were more pronounced in patients of this group. The roentgenograms showed the displacement to be more pronounced than in the patients of the preceding group.

Results of treatment of chronic slipping with marked displacement. a. Nine patients with unilateral chronic slipping of marked degree, seen 1 month to 3 years after onset of symptoms, were treated by a short period of bed rest or with crutches and no weight bearing of the affected leg for a few weeks. To this group belonged the case of a 25 year old girl with marked hypopituitarism and delayed closure of all epiphyses (results—7 hips, 3 1 hips 4).

b. Three patients one with bilateral chronic slipping of marked degree, seen 9 to 12 months after onset of symptoms were treated by plaster cast immobilization for 4 to 6 months. No further slipping was noted in the hip of any of these patients. The results were satisfactory because the pain disappeared in all the patients so treated (results—4 hips, 3).

c. Two patients, seen 18 and 24 months after onset of symptoms were treated by manipulation of the hip under anesthesia, followed by plaster cast immobilization. No reduction of the slipping was obtained in either case and no necrosis of the femoral head was observed. Two years after the manipulation it was noted in one of these patients that the joint space was very narrow and there was great restriction of all hip motions. This case will be discussed later (results—2 hips, 4).

d. Three patients with unilateral chronic slipping of marked degree seen 6 to 12 months after onset of symptoms, were treated by drilling and pinning of the upper femoral epiphysis. One of these patients was a 20 year old boy who had hypopituitarism with delayed epiphyseal closure. His other hip was treated for a preexisting. The result in each of these patients was satisfactory although they had moderate residual limitation of hip motion (result—3 hips, 3).

e. Eight patients with unilateral chronic slipping of marked degree seen 6 months to 4 years after onset of symptoms, were treated by different types of osteotomies.

facial arthroplasty was performed in May 1939. At the operation the articular cartilage of the femoral head was found to be eroded and pitted. This condition was most pronounced in the region of the fovea centralis. Numerous fibrous adhesions were present and probably were the cause of the marked limitation of motion. Microscopic examination revealed hyperemia of the synovia which contained a few chronic inflammatory cells. Irregular enchondral ossification was present in the deep layers of the joint cartilage covering the femoral head. Some degree of this same process was present in the cartilage covering the acetabular cavity. The joint cartilage was thinned because of ossification of its deeper layers. The marrow spaces of the subchondral bone contained essentially normal marrow which was devoid of inflammatory cells (Fig. 6, e and f).

The patient was last seen in February 1947 and had fairly good range of useful motion in both hips. The joint space of the right hip was wide but the contours of the femoral head were irregular.

CASE 2. A 14 year old girl was admitted to hospital in September 1945. The entrance complaint was limp and pain in the right hip aggravated by wet weather of 7 months duration. Examination revealed fairly good range of motion in the right hip except for absent internal rotation. Marked atrophy of the upper femoral metaphysis was seen on the anteroposterior roentgenogram and the lateral view revealed a mild posterior displacement of the femoral head (Fig. 7, a and b). The right upper femoral epiphysis was drilled and pinned in December 1945 without any previous hip manipulation. Four months after the operation the range of motion became very restricted, and the roentgenograms showed marked narrowing of the joint space. The femoral head appeared normal. Sedimentation rate, white blood count, hemoglobin, and other laboratory examinations were completely normal. The narrowing of the joint space and the limitation of motion progressed and in December 1946 the right hip was fixed in a position of 40 degrees flexion. The roentgenograms at that time showed a very irregular subchondral line with spreading ossification into the deep layers of the joint cartilage of the femoral head (Fig. 7, c). The threaded Steinmann pins were then removed and the hip was gently manipulated under anesthesia. Only 30 degrees of flexion extension motion were possible. The patient was last examined in May 1947 when only a few degrees of flexion extension motion could be detected in the right hip joint (Fig. 7, d). The left hip has always been completely normal.

CASE 3. A 15 year old boy was first admitted to hospital in August, 1942 in this clinic. The entrance complaint was pain and limp in the right hip of 3 weeks duration. The patient had only 35 degrees of active flexion in the right hip. Passive motion was almost normal. Roentgenograms showed a preslipping of the right femoral epiphysis. The patient was advised to use crutches and limit weight bearing on

the affected limb. Seven months later an acute slipping occurred in the right hip. The patient was not seen until 5 months after the accident, when the right hip was manipulated under anesthesia. The position of the displaced head was not changed during the manipulation. Necrosis of the femoral head did not occur. One year later there was marked limitation of motion in the hip joint with irregularity of the subchondral line of the femoral head and acetabulum and marked thinning of the joint space. An intertrochanteric osteotomy was performed to correct flexion and external rotation contracture which had developed in the right hip joint. The patient was last seen 3 months later in September, 1944, when the examination revealed very limited motion in the right hip joint. The left hip was clinically normal but the roentgenograms taken on the last admission showed marked narrowing of the joint space in both hips.

We have been unable to determine the nature of the process responsible for the symptoms described in these 3 patients. In only one case was material for histological examination obtained when the process was quiescent. The lesions resembled the quiescent stage of a mixed type of arthritis.

SUMMARY

Seventy three patients with slipped upper femoral epiphysis seen at the University Hospital in Iowa City from 1932 to 1947 have been reviewed. Nineteen patients had bilateral slipped epiphyses.

This series of patients was divided into 5 groups as follows:

1. Preslipping stage—5 patients, 1 with bilateral preslipping. This potentially dangerous stage was treated best by drilling and pinning as soon as the diagnosis was established.

2. Acute slipping or fracture separation of upper femoral epiphysis—19 patients, 1 with bilateral acute slipping. Best results were obtained by early and gentle reduction of the fracture separation maintaining the reduction by 2 or 3 threaded Steinmann pins. A bone graft used to maintain fixation may be preferable. It is advised that when these patients are seen more than 2 weeks after the accident no attempts should be made to reduce the slipped epiphysis. An intertrochanteric osteotomy may give good results in these cases without damaging the blood supply to the femoral head.

3 Chronic slipping with minimal to moderate displacement—31 patients 4 with bilateral chronic slipping Rest from weight bearing or plaster cast immobilization gave good results the epiphysis closed on an average of 9 months Drilling and pinning of the upper femoral epiphysis offered assurance against further slipping or acute slipping the epiphysis closed on an average of 6 months and the patients had free use of the extremity 1 month after the operation

4 Chronic slipping with marked displacement—21 patients 5 with bilateral chronic slipping The prognosis in this type is poor under any form of treatment This should be directed first toward preventing further slipping and hastening fusion of the epiphysis Neck osteotomy will restore the alignment of the femoral head and neck but loss of blood supply to the femoral head is too frequently the price Better results may be obtained by drilling the upper femoral epiphysis followed by an intertrochanteric osteotomy performed un-

der vision through an anterior incision with rotation and displacement of the distal fragment medially

5 Residual deformities—4 patients 1 with old bilateral slipping

The clinical symptoms physical and roentgenographic findings and results of various types of treatment in these groups are recorded.

Three patients developed early and marked narrowing of the joint space and are presented in some detail A fascial arthroplasty was performed in one of these patients The specimens obtained at operation revealed lesions similar to the ones seen in the quiescent stage of a mixed type of arthritis No evidence of inflammation was noted

Nevertheless during the past 35 years in which this operation has become so widely accepted there have been sporadic attempts to develop operative procedures that would sufficiently answer the need for wide excision and yet preserve anal continence. This has been particularly true where the lesion was situated in the lower sigmoid or rectosigmoid junction. Lockhart Mummery in 1908 and Balfour in 1910 reported their experiences with anastomosis over a rectal tube.

A new drive for eliminating the permanent colostomy was initiated in 1935 by Devine who presented a technique for colostomy of the transverse colon which would completely defunction the distal colon permitting later resection and anastomosis followed by closure of the colostomy. No doubt the principle of this procedure is sound but the operation was not widely accepted and with the new antibiotic agents of recent years it will probably become less popular.

In 1937 Horsley presented his technique for resecting the rectosigmoid which consisted of a preliminary cecostomy and an open anastomosis deep in the pelvis. Since 1939 reports of cases of re-establishment of bowel continuity and preservation of the anal sphincter have come from Arnold, Bacon, Babcock, Dixon, Dunphy, Fallis, Murray and Wangersteen. The individual techniques, the indications for and selections of, cases have varied but their writings exhibit a common desire to escape the permanent colostomy.

Previous to 1941 I had occasionally restored intestinal continuity with lesions of the lower sigmoid but never if the lesion involved the rectosigmoid. During the year 1941 and early months of 1942 I anastomosed the terminal ileum to the mid or lower rectum in 7 cases. This operation of ileorectostomy was done because with wide excision of the upper sigmoid at that time it was impossible to anastomose the colorectal ends low in the pelvis. Of these 7 patients 3 established fairly satisfactory bowel habits even though the terminal ileum emptied directly into the mid or lower rectum. In 4 of the cases with anastomosis to the lower rectum there was a troublesome diarrhea. This procedure has been discontinued except in cases of multiple polyposis with

Fig. 1. In the anal canal, 3 modes of spread are considered. The anal skin is drained by lymphatics leading to the superficial inguinal nodes. Above the skin margin is an intermediate area which may drain laterally to under surface of the levator ani and then through this muscle to the hypogastric nodes or directly upward into intramural lymphatics. The upper anal canal and lower rectum may drain into the hypogastric nodes or progress upward along the pararectal nodes. Observations suggest that pararectal and paracolic nodes tend to drain into the intermediate nodes but if these become blocked, the spread is likely to be directly upward along the paracolic nodes.

rectal cancer. The more recent interpretation of lymphatic spread has resulted in a less radical excision of the sigmoid colon and rectum which permits end-to-end anastomosis deep in the pelvis.

Can we conform to the principle of radical cancer surgery in carcinoma of the rectum and rectosigmoid and still preserve the sphincter mechanism? This requires some modifications of Miles' interpretation of the mode of spread—namely upward laterally and downward. A challenge to Miles' teachings is supported by the study of lymphatic glands in surgically removed specimens and in autopsies by West, Huer, Gabriel, Dukes and Bussey, Gilchrist and David and Coller, Kay and McIntyre. These studies reveal that dissemination of cancer cells in a downward direction is unusual unless the lymphatics above the tumor are blocked by metastasis. Intramural spread of cancer cells below the lower margin of the tumor is a rarity and studies by the aforementioned investigators suggest that a clearance of at least 1 inch and preferably 2 inches is a

re establishment of bowel continuity is usually attempted. Three types of operative procedures have been selected to permit sphincter preservation. These are abdominal dissection, resection and anastomosis; abdominal dissection with perineal resection and anastomosis; and perineal dissection with perineal resection and anastomosis.

THE ABDOMINAL DISSECTION WITH RESECTION AND ANASTOMOSIS

The abdominal dissection with resection and anastomosis is selected when the upward spread is limited as heretofore discussed and the lower margin of the lesion is at least 7.5 centimeters (3 inches) from the anal margin. The actual lower margin of the tumor frequently varies from the preoperative estimate by rectal examination. The sacculated structure of the rectum permits elongation of the rectum when pulled upon from above and as the operation progresses the lesion may actually be several centimeters higher than was anticipated. Again one should not always depend on this sacculatation resulting in an elevation of the lesion. If we are to play safe

Fig. 4. The posterior sutures have been tied. One anterior catgut suture with knot on mucosal wall to initiate inversion has been inserted. Remaining sutures will be figure-of-8 or mattress silk sutures.

Fig. 5. A single layer of interrupted figure-of-8 or mattress silk sutures complete the anastomosis.

with our present knowledge of cancer extension in this region, the rectum should be resected at least 2.5 centimeters (1 inch) below the lower margin of the tumor, and we feel that 3.5 centimeters (1½ inches) to 5 centimeters (2 inches) is preferable, even though in low lying lesions this may impede anastomosis from within the abdomen. An open type of anastomosis has been used because in lesions below the lower sigmoid the difficulties with closed anastomosis seem greater than the advantages. A technique has been developed which has served well. Just before the operation is started, a large rubber catheter which has been attached to the suction machine is inserted into the rectum to make sure that it is empty. After the usual study of the vascular pattern the superior hemorrhoidal vessel or its branches are properly ligated to assure adequate vascularization of a sufficient upper segment of sigmoid to permit anastomosis. However, one must remove an adequate zone of probable lymphatic spread or extension. It is usually necessary to divide the middle hemorrhoidal vessels, yet there appears to be adequate vascularization of the lower rectal stump as noted by bleeding from the rectal wall. A right angle clamp is applied (Fig. 2) at

Fig. 6 A supplemental cecostomy is performed by puncturing a mushroom catheter into the cecum. The rectal wall is inverted and the cecum fixed to the parietal peritoneum.

least 2.5 centimeters (1 inch) below the tumor margin and preferably 4 to 5 centimeters (1.5 to 2 inches). Two short nosed right angle clamps grasp either side of the rectal wall just below the right angle clamp. The rectum below the crushing clamp can then be severed with an angled knife without too much difficulty. At a level high enough above the tumor to be above the level of direct lymphatic spread and through viable sigmoid a soft bladed clamp is applied or a rubber drain or tube is clamped or tied around the bowel. This is done several inches or more above the level of transection in order to permit open anastomosis low in the pelvis. After the bowel segment with the tumor is removed the remaining clamps on the lower segment are replaced by two long catgut sutures. These are permitted to hang over the pelvis to steady the rectal stump. The two ends of the bowel are prepared for bringing into apposition by inserting a long catgut suture on either side of the midline (Fig. 3) in the posterior aspect. The ends of the bowel are guided along these sutures to the juxtaposition and as these sutures are tied with knots on the mucosal side, the rectal and sigmoidal walls are inverted. A similar catgut suture is placed anteriorly (Fig. 4). The anastomosis is then secured by accurately placing a single layer of interrupted

figure-of-8 silk sutures (Fig. 5). A rubber Penrose drain is placed in the hollow of the sacrum and the peritoneal margin of the pelvic floor is approximated above the drain and around the sigmoid at a level above the line of anastomosis.

Before the abdomen is closed a modified Gibson cecostomy (Fig. 6) using a mushroom catheter is accomplished through a small muscle splitting incision on the right side. It is our observation that a patient is more comfortable with a cecostomy tube for decompression than with nasogastric or nasointestinal suction and probably a cecostomy is a much more efficient safety factor in colon anastomosis. In my experience, this type of cecostomy has always closed spontaneously if obstruction is not present.

The patient is then turned over on his left side, a small incision is made along the coccyx through the fascia propria into the space in the hollow of the sacrum to permit delivery of the previously placed rubber drain.

Placing the sutures deep in the pelvis is quite difficult and awkward and not infrequently there must be some failure in the suture line. However we must not be too disturbed about this because certain experiences in rectal injuries during World War II substantiate the fact that proper healing will oc-

Fig. 7 The abdominal dissection has been completed and the pelvic peritoneum is loosely closed around the sigmoid. Abdominal incision is closed and the sigmoid and rectum are pulled out of posterior incision.

cur It was found that in rectal injuries by single or multiple shell fragments life would be saved and rectal healing would usually take place if the fecal contents were diverted by a colostomy and proper posterior drainage of the perirectal space in the hollow of the sacrum was established. Although cecostomy does not completely sidetrack the bowel contents suction applied to the tube and proper posterior drainage have given excellent results. The amount of posterior drainage has varied. At times it is minimal and again there may be considerable drainage with a fecal odor or even frank feces. Generally the tracts have closed within a week or two although in 2 cases closure took several months.

ABDOMINAL DISSECTION WITH PERINEAL RESECTION AND ANASTOMOSIS

A second type of operative procedure may be indicated when the lower margin of the tumor is at or just below the 7.5 centimeter (3 inch) level. Also it may be suspected before operation and confirmed at the operating table that the anastomosis could not be completed from within the abdomen because of a small pelvis. In this event the abdominal dissection is car-

Fig 9. Completion of posterior anastomosis. An outer layer of interrupted silk mattress or figure-of 8 sutures is inserted.

ried out in the usual manner but the rectum is not transected. It is determined that sufficient viable sigmoid remains to be brought down for anastomosis and the level of transection is labelled by a small black suture. The peritoneum of the pelvic floor is closed but not too snugly around the sigmoid. A Gibson type cecostomy is established, the abdomen is closed and the patient is placed in the prone position with hips elevated or placed in the left lateral Sims position. An incision is made over the sacrum and coccyx; the coccyx is excised and the sigmoid and tumor are delivered (Fig. 7). Sufficient further dissection is done to permit adequate transection below the lower margin of the tumor. A soft bladed clamp is applied above the level of the identifying black suture. A crushing clamp is applied below this and the sigmoid is severed. Another crushing clamp is applied an inch or more below the tumor margin. Several Allis clamps steady the lower segment as the rectum is severed below the crushing clamp. The lower stump is swabbed out with sulfanilamide solution. The end-to-end anastomosis is accomplished by inserting interrupted catgut sutures in such a manner as to leave the knots on the inner or

Fig 8. Posterior anastomosis with inner row of interrupted catgut sutures. To facilitate procedure all posterior sutures are inserted and then tied.

Fig. 9. Posterior dissection (full) of rectum and anastomosis. Anastomosis completed (Figures 8 and 9).

mucosal wall (Fig. 8). Interrupted mattress sutures of silk are inserted around the entire circumference to complete the anastomosis (Fig. 9). By means of an accessory rubber glove the line of anastomosis is examined from within the rectum. The wound is well irrigated with warm saline solution and sulfanilamide powder is frosted throughout. A Penrose drain is placed in the hollow of the sacrum. The remaining levator muscle tissue and fascia are closed around the rectum with interrupted chromic catgut sutures. These are supported with several heavy silk sutures which also approximate skin and subcutaneous structures. If a supplementary cecostomy was not established a rubber rectal tube may be inserted up through the line of anastomosis and then fixed to the anal skin. Which is the better method is difficult to say at this time.

PERINEAL DISSECTION WITH PERINEAL RESECTION AND ANASTOMOSIS

The third type of anastomosis for carcinoma of the rectum will be indicated in relatively few cases. One hesitates to say that it is fundamentally sound because one is probably too conservative in removal of the tissue above the lesion which is in the zone of established

spread. However it may be the operation of choice in some poor risk patient when the entire lesion is palpable per rectum. Also it may be done in selected cases in which the tumor is small.

The lower margin of the tumor is at least an inch above the upper margin of the muscular anal canal and the upper margin can be palpated by the examining finger. The tumor should not be fixed to surrounding structures and should be confined to the mucosa. Murray has recently reported 15 cases in which operation consisted of posterior resection and anastomosis. The tumor area is approached by a midline incision over the sacrum and coccyx extending to within one half inch of the anal margin. The coccyx is removed and possibly the fifth sacral body. The tumor is freed as for a posterior excision after the method of Lockhart Mummery. The peritoneum is opened close to the rectal wall and sufficient sigmoid is delivered to permit excision of the tumor segment and anastomosis of the rectum to the rectal or anal stump (Fig. 10). Anastomosis is accomplished as described in the operation for abdominal dissection with posterior excision and anastomosis (Figs. 8, 9). The wound is liberally flushed with saline and frosted with sulfanilamide. In these cases cecostomy has been omitted but a $\frac{1}{2}$ or $\frac{3}{4}$ inch tube has been inserted into the anorectal canal to above the line of anastomosis. The perirectal space is drained and tissues closed as previously described. The tube is stitched to the perianal skin. With our limited experience in this type of operation we are undecided as to the necessity for a supplementary cecostomy. Further experience may prove that it is desirable.

It is our opinion that a nonabsorbable sulfonamide preferably sulfathaladine is indicated for 4 to 5 days preoperatively in the preparation of a patient for anastomosis. With open types of anastomosis some soiling takes place and these drugs may be a safety factor against invasive infection. On several occasions rather gross soiling has occurred without event. Penicillin has been given postoperatively in 25,000 to 50,000 unit doses every 4 hours beginning immediately and continued for 5 to 10 days. In several cases where a marked break in technique occurred surprisingly clean posterior wounds have resulted.

ANALYSIS OF CASES

During a recent 6 month period, I saw 18 patients with carcinoma of the rectum or rectosigmoid. Surgery was advised in all but 3 instances. One of these 3 patients had a rather large tumor fixed to the sacrum and surrounding structures, with urinary incontinence secondary to a previous perineal prostatectomy, and electrocoagulation was selected as the method of treatment. Two other cases were labelled inoperable because of extensive local disease and evidence of distant metastasis. This is an 84 per cent operability rate. Of the 15 patients explored 13 (72 2 per cent of the 18 cases) were resected. Of the 13 resectable lesions only 2 were subjected to abdominoperineal excision with permanent abdominal colostomy. In the other 11 patients (84 6 per cent of the resectable lesions), colostomy was avoided by anastomosis of the sigmoid, rectal or anal segments. Of the 11 cases 8 were done by abdominal resection and anastomosis 2 by abdominal dissection with posterior resection and anastomosis and 1 by posterior dissection resection and anastomosis. There was one hospital death in a case of abdominal resection and anastomosis in a large heavy set individual when probably the result would have been different if a combined abdominoperineal excision had been done. This is a mortality rate of 6 6 per cent for the patients subjected to operation and a mortality rate of 7 6 per cent for patients subjected to resection. This mortality rate in a rather small series of cases in which where sphincter preservation has been accomplished in 84 6 per cent of the cases compares quite favorably to the mortality rate in cases in which the avoiding of colostomy is not attempted. However I believe a higher potential mortality exists as the operation is more difficult, more time consuming and the incidence of infection is undoubtedly higher where an awkward anastomosis is attempted. Before the advent of the antibiotic agents now available and the more energetic use of blood plasma and whole blood transfusions, resection and anastomosis of the rectal segments carried a much higher morbidity and mortality rate, and this restricted the enthusiasm for sphincter preservation. In obese and poorer risk patients abdominoperineal ex-

cision or posterior excision without anastomosis would seem to carry less hazard

CONCLUSIONS

At this time, very few conclusions can be drawn as to the probable end results over the 5 and 10 year periods in these operations for restoring intestinal continuity after resection of the rectum and rectosigmoid. In general, the sphincter function has been adequate and in most cases remarkably satisfactory. Theoretically as based on anatomical and pathological dissection an effort should be made to prove or disprove the expediency of this less destructive operative procedure but only after another 5 years or more with reports from numerous authors can the true evaluation be made. In the interval, however, some patients will have had a happier existence for a longer or shorter period because of a retained sphincter mechanism. If the end results in 5 year cures or ultimate cures do not vary more than 5 to 10 per cent from the results of abdominoperineal excision with permanent colostomy, the operation should be one of choice or at least patients should be given an opportunity to make the decision. Our present evaluation of the more conservative operation as regards morbidity and mortality is predicated on results obtained when we were unable to exercise the finer details of judgment, technique, preoperative and postoperative care, and control of infection.

TISSUE PROTEIN DEPLETION

A Factor in Wound Disruption

S ARTHUR LOCALIO M.D. Med Dir JAMES L. CHASSIN M.D., and
J WILLIAM HINTON M.D. New York New York

WOUND disruption has been reported in 15 per cent of abdominal operations (9). This occurrence is associated with a mortality of 35 per cent, and a train of complications such as intestinal obstruction, peritonitis, and incisional hernia. The more common etiological factors are technical errors, poor suture material, compromise of the nerve and blood supply of the wound, infection, obesity straining by coughing, vomiting or distention, debilitation by systemic disease, vitamin C deficiency (10), and hypoproteinemia (16, 17, 33). This study concerns the relationship between protein depletion and wound disruption.

Clark in 1919 showed that a diet high in protein shortens the lag period in the repair of experimental wounds. Such a diet accelerates the return of the wound to maximal tensile strength (11). Utilizing a serial tensile strength method (19), Localio and Hinton (20) have shown that gain in wound strength is markedly delayed in hypoproteinemic rats.

Thompson and associates were the first to implicate protein deficiency as a major factor in postoperative wound disruption. Koster and Shapiro (17) shortly thereafter demonstrated that in cases of human wound dehiscence the mean serum protein concentrations were lowered. Serum protein levels of less than 6.0 grams per cent were noted in 42 per cent of the 40 cases of wound disruptions reported by Koster and Kasman (16).

In reviewing several cases of evisceration which had the benefit of meticulous operative technique, nonabsorbable suture material (cot-ly), massive doses of vitamins preoperatively, and in which no wound infection occurred, we noted normal plasma protein levels in all of the patients. However, protein deficiency was suspected clinically. This led us to question whether significant depletion of the tissue proteins might occur in the face of essentially normal serum protein levels, and whether the concentration of tissue proteins might in such cases be more directly related to wound healing than the level of the circulating serum proteins. Consequently, the attempt has been made to compare tissue protein concentrations in cases of wound dehiscence with those of normal patients.

In the course of these studies we have been impressed with the need for clarification of the present terminology. For instance the term "hypoproteinemia" is far too often used as a synonym for protein deficiency in general. Elman (8) states that the term protein deficiency rather than hypoproteinemia has much to recommend it as a more accurate and useful designation. In order to provide a simpler terminology it is proposed that the term "hypoproteinism" be adopted in referring to the depletion of protein from the tissues of the body in general, whether or not serum protein concentrations, as determined by the usual clinical methods, are significantly reduced. "Hypoproteinemia" should be used only to describe a subnormal serum protein concentration.

MATERIAL

The patients were chosen from the Surgical Services of the New York Post Graduate Hospital and the Fourth Division of Bellevue Hospital and the Doctors Hospital, New York.

A control group of 17 individuals was made up of patients who were undergoing laparotomy for benign conditions and who were considered on the basis of history and physical examination to be in a good state of nutrition.

The second group of 21 consisted of patients suffering from a debilitating disease, and who were therefore suspected of hypoproteinism.

Because of their preoperative clinical condition they were also considered to be potential candidates for wound dehiscence. Fourteen had gastrointestinal carcinoma or peptic ulcer.

A third series of 17 patients had experienced postoperative wound disruption.

METHODS

In all cases blood samples were drawn for serum protein determinations either immediately before or after operation. The method used for total protein concentration was modified from Koch and McMeekin. The albumin fraction was isolated according to Howe. Tissue protein concentrations were determined by a technique similar in principle to that used by Elman and Helfetz (7) namely:

Tissue specimens consist of about 2 to 3 square centimeters of fascia, peritoneum and muscle. The specimens are taken during operation from the rectus muscle and sheaths superior to the semilunar fold of Douglas. They are carefully dissected free of fat and other adherent tissue, wrapped in gauze slightly dampened with isotonic saline, and rushed to the laboratory. They are weighed immediately to the nearest milligram on an analytical balance. Each specimen is then placed in a 50 cubic centimeter volumetric flask with about 0.5 cubic centimeter of concentrated (100 gm per 100 c.c.) sodium hydroxide and 8 to 10 cubic centimeters of isotonic saline. The flask is placed in a boiling water bath until the tissue is completely digested (30 to 60 minutes). Upon cooling, saline is added to the 50 cubic centimeter mark. An aliquot consisting of 3.0 cubic centimeters is placed in a Nessler protein tube and the total nitrogen is determined by the same method as for serum protein. The resultant tissue nitrogen concentration is multiplied by 6.25 to give the protein concentration in percentage of wet tissue.

RESULTS

Table II lists the results to the group of 21 patients who were considered clinically to be in a state of hypoproteinism. All but 6 have normal serum protein levels. The tissue protein concentrations vary considerably. In comparing the fascial protein concentrations of this group with those of the normal patients of Table I it is seen that no normal patient had a fascial protein concentration of 24.0 per cent or below. If 24.0 per cent is chosen as the lower limit of normal, then 11 of the 21 debilitated patients in Table II demonstrate a diminished fascial protein concentration despite the fact that 5 of these 11 patients had preoperative amino acid therapy. Six had normal serum proteins at the time of operation.

The 17 cases of evisceration (Table III) have significantly lower mean tissue protein concentrations than the patients of the normal control group. This is illustrated in Table IV. The mean fascial protein concentration of the patients who had wound disruptions is also significantly lower than that of the debilitated patients who did not suffer disruption as shown in Table V. Serum protein levels were low in only 4 of the 17 cases of evisceration, even though the determinations were made on blood drawn at the time of evisceration. Unfortunately, serum albumin levels are not available for most of these patients.

DISCUSSION

It is generally agreed that a subnormal serum protein concentration denotes protein deficiency. The converse, however, need not be true. Our results indicate that significant tissue protein depletion may exist in the face of normal serum protein levels, which by present clinical standards are normal. In this study, using the method of Koch and McMeekin, we have considered 6.0 grams per cent to be the lower limit of normal for total serum protein concentration in agreement with Kagan and Trevorrow.

*Peritoneum taken below semistarvation fold of Douglas and therefore omitted from consideration.

There are many reasons why the serum protein level may be misleading as an index of the state of protein nutrition. Reduction in the total circulating serum albumin is often accompanied by considerable decline in plasma volume, thus tending to maintain a normal serum protein concentration (18, 22, 24, 25, 28). Meyer and Kozoll attempt to detect this hemoconcentration by serial determinations of the hematocrit. Unfortunately however some of the most crucial surgical patients suffer from various degrees of anemia simultaneously with hypoproteinemia, thus tending to nullify the hemoconcentration effect.

Determination of the serum protein level without evaluating the albumin fraction frequently will fail to disclose a hypoalbuminemia, which is masked by the presence of hyperglobulinemia secondary to chronic infec-

tion (13, 25) and other stimuli. Thus, in some instances, a state of hypoproteinemia may be detected by albumin determinations but not by the total serum protein concentration. Unfortunately the accuracy of the albumin determination, as routinely performed in many laboratories, leaves much to be desired.

If it is true that the total serum protein concentration is not a reliable index of hypoproteinemia, the question then arises as to whether accurate determination of the albumin fraction will solve this problem. Elman and his co-workers (6, 8, 31) in this regard have emphasized the work of Weech who noted a prompt hypoalbuminemia in dogs on a protein-free carrot diet. That this is not necessarily applicable to human patients can be seen from the fact that in young men placed on a semistarvation diet with a protein con-

tent of only 49 grams a day for a 6 month period, the plasma protein fell only slightly and the A/g ratio remained within normal limits (14). This was despite the fact that these 34 men lost an average of 24.5 per cent of their body weight and all developed significant edema. Other recent studies (5) have confirmed the finding of normal serum albumin and total protein concentrations in the presence of famine edema. No clear explanation of this phenomenon was offered. Thus, even the serum albumin level is not a consistent index of hypoproteinemia.

Ravdin predicted that if the means to determine it were available, the first effect of

protein undernutrition is a reduction in the amount of protein stored in the tissues of the body since every attempt is made to maintain the serum protein concentration at a near normal level. However it has never previously been demonstrated by direct measurement that depletion of tissue protein actually does occur in humans in the presence of normal serum protein concentration. Our results demonstrate that depletion of the fascial protein may be revealed by the method described at a time when the serum protein concentration is within normal limits. The muscle nitrogen concentration is not as sensitive an indicator of early hypoproteinemia. One factor

may be the rapidity with which muscle loses moisture. It has been noted that a 250 milligram sample of wet muscle may lose as much as 20 milligrams per minute during weighing thus is introduced a serious technical error.

In view of the acknowledged importance of the fascial layer in wound healing it is of interest that the lowest tissue protein values were encountered in the fascia of patients with wound disruptions, indicating that severe

hypoproteinemia frequently occurs in these cases despite apparently normal serum protein levels. It is therefore considered that the degree of protein depletion of the fascia is more directly related to failure of wound healing than is the degree of serum protein depletion as measured by total protein concentrations.

Outstanding among the recent advances in the field of protein metabolism is the concept of 'dynamic equilibrium' which governs the

TABLE IV — COMPARISON OF MEAN TISSUE PROTEIN CONCENTRATIONS IN CASES OF WOUND DISRUPTION AND IN NORMAL PATIENTS

	Normal patients per cent	Wound disruptions per cent	Differences per cent	Statistical significance ^a
Mean protein concentration of fascia	40.00	18.73	21	t = 4.36 P less than .01 Therefore significant
Standard deviation	3.67	3.3		
Mean protein concentration of peritoneum	24.90	9.77	15	t = 3.78 P less than .01 Therefore significant
Standard deviation	3.90	2.1		
Mean protein concentration of muscle	70.25	76.8	6.5	t = .42 P = .68 Therefore probably insignificant
Standard deviation	26	3.53		

^aThe statistical significance of the difference between the two groups was tested by the t-test as described by Fisher, R. A. in *Statistical Methods for Research Workers*, 7th ed. Edinburgh, Oliver and Boyd, 1954. The standard deviation of the difference between the respective means was calculated by the formula:

$$S.D. \text{ Diff.} = \sqrt{\frac{\sigma_1^2}{N} + \frac{\sigma_2^2}{N}}$$

where σ_1 and σ_2 are the standard deviations of the normal and the disruption groups respectively and N and N are the number of cases in each group respectively.

interchange of proteins between the blood and tissues (31). Following rapid plasma protein depletion by plasmaphoresis, a normal dog may re-form as much as 40 to 60 per cent of its total circulating plasma proteins even during fast (23). Whipple and his co-workers (23) showed that the source of the regenerated serum proteins were reserve stores of protein metabolites existing in various tissues. The nature and location of the tissues reserves have posed a difficult problem. It has been suggested by Addis (1, 2) that the liver has a large fraction of labile protein which may be utilized by the organism during fast. The composition of this reserve protein is apparently identical with the total protein of the liver cells (21). That the dynamic equilibrium between serum and tissue proteins operates in the reverse direction may easily be illustrated by maintaining animals in positive nitrogen balance for indefinite periods of time on protein free diets supplemented only with intravenous injections of plasma (37). In a healthy organism, of course, it is expected that the tissue cells are capable of participating in the

TABLE V — COMPARISON OF TISSUE PROTEIN CONCENTRATIONS IN CASES OF WOUND DISRUPTION AND IN DEBILITATED PATIENTS

	Debil- itated patients per cent	Wound Disruptions per cent	Differences per cent	Statistical significance

dynamic equilibrium of protein metabolism and of extracting from the total pool of body protein the metabolites necessary for their specific functions. It may be however that this equilibrium is disturbed in the diseased state. This suggests another possible explanation for the disparity between the protein concentration of the tissues and the serum, as noted in Table III.

One may account for the disparity between the determined protein concentrations of the tissues and the serum in several ways. The serum protein concentration may not reflect a reduction in total circulating proteins because of a contracted plasma volume. The total serum protein level may be normal in the face of hypoalbuminemia. Normal total serum protein and albumin levels have been shown to occur in severe hypoproteinemia and even in nutritional edema (14, 30). The body may attempt to maintain homeostasis of the serum protein concentration at the expense of tissue proteins (29). In diseased states there may be breakdown or delay of the dynamic equilibrium between serum and tissue proteins.

By way of practical application our findings serve to emphasize the study of the patient as a whole rather than of his serum protein concentration. The extensive literature on "hypoproteinemia" in surgery has focused considerable attention upon the results of the serum protein determination alone. Unfortunately too often a normal serum protein level has been interpreted to be an adequate

index of the preoperative patient's protein nutrition. Needless to say a normal serum protein concentration often affords a sense of security that is entirely false and the surgeon may underestimate badly the quantity of protein necessary properly to prepare his patient for major surgery. Calculation of the probable protein needs of the preoperative and post-operative patient should be based upon the nature and duration of the lesion, the dietary history, loss of weight and clinical appearance and not solely upon the result of a serum protein determination. Cases of gastrointestinal carcinoma (3) and peptic ulcer (27) for example should receive intensive preoperative protein therapy. This is especially true because in cases involving gastric or intestinal anastomoses, failure of wound healing at the site of anastomosis is tantamount to catastrophe. Varco has recently provided a practical guide to the methods of protein therapy.

Since our data are at present incomplete with regard to the relationship between tissue proteins and the serum albumin fraction studies in this direction are now being pursued and will be reported later. Preliminary findings indicate that under certain conditions, hypoproteinism may occur even with normal or borderline albumin concentrations.

SUMMARY AND CONCLUSIONS

1. The level of tissue proteins was determined in fascia, peritoneum and muscle in normal humans.

2. Estimation of the protein concentration of the fascia is offered as a means of ascertaining the state of protein nutrition.

3. Depletion of the protein of the fascia seems to be an important factor in the etiology of wound disruption.

4. The total serum protein may be maintained within normal limits even in the face of significant depletion of the tissue protein. Hence in humans, the serum protein concentration does not constitute an adequate index of the state of protein nutrition.

5. The term hypoproteinism is proposed to describe the state of depletion of tissue protein whether or not this is accompanied by simultaneous depletion of serum protein.

VAGOTOMY

ALTHOUGH numerous debatable issues remain regarding the exact place that vagotomy should assume in the treatment of peptic ulcer since Dragstedt and his associates focused attention on this procedure in 1943 certain aspects of the subject have become defined with a fair degree of clarity. It therefore seems appropriate that some comment be made at this time regarding what has been learned and the deficiencies in our knowledge which still exist. Many of the physiologic effects of bilateral section of the vagus nerves in man have been repeatedly demonstrated and verified. It is of more than 10

and gastric hypomotility results. Other less significant effects also have been noted. Vagotomy does not eliminate sensory stimuli from the stomach or duodenum.

The influence of vagotomy on the accessory organs of digestion has been incompletely investigated from a physiologic point of view. To date no serious deleterious effect on the function of these structures has become apparent. Certain symptoms, such as diarrhea and abdominal cramps which occasionally occur after vagotomy have not been satisfactorily explained. Likewise our knowledge is incomplete concerning the physiologic effects of vagotomy on the small intestine and large bowel. A most important question which has not been answered definitely as yet is how long the effects of vagotomy persist. Certain experimental evidence (Vanzant) as well as some clinical evidence presented by Moore suggests that the effects of vagotomy may be temporary. Results of other clinical studies do not substantiate this point of view. Clarification of this important point will require further time. Various methods of dealing with the cut ends of the vagus nerves have been devised and tried in order to obviate possible regeneration and restoration of vagal continuity. Physiologic studies made several years or more ago determined that vagotomy to determine

interested in the subject. Thus Grimson Colp and many others agree that thoracic vagotomy alone should not be employed as a routine operation for the treatment of duodenal ulcer. This is largely because of failure of the stomach to empty properly in a significant percentage of cases in which the thoracic approach has been used. This failure may occur even despite lack of evidence preoperatively to suggest pyloric obstruction. In addition this procedure affords no opportunity for verification of the lesion at the time of operation which in itself is not an inconsequential consideration.

In contrast most all agree that vagotomy alone constitutes a most welcome contribution to the treatment of jejunal ulcer which occurs after gastric resection. In fact it is thought by many that this lesion constitutes the most definite indication for vagotomy today. Opinion is less well formulated on the use of vagotomy alone in the management of jejunal ulcer which follows gastroenterostomy for under these circumstances the second phase of gastric secretion remains active.

At present most discussion revolves around abdominal vagotomy associated with gastroenterostomy as the operation of choice for duodenal ulcer. According to Dragstedt this is a most satisfactory operation, however Walters and others have reported somewhat less brilliant results. A final decision on this subject will require the lapse of more time. At the time when end results are reported, evidence also should be presented regarding the percentage of cases in which the postoperative finding suggested either complete or incomplete section of all vagal fibers. I have found it more difficult to feel confident that all vagal fibers were sectioned when an abdominal rather than thoracic approach is used. Not all surgeons have this opinion. The abdominal approach affords the obvious advantages of

permitting direct inspection of the lesion and the abdomen in general in addition to an opportunity to perform any associated surgical procedure that is indicated. Theoretically the operation which should afford the greatest chance to cure duodenal ulcer and prevent subsequent jejunal ulcer is vagotomy associated with high resection of the stomach. It seems possible that in a small group of selected cases this operation may have a certain field of usefulness.

Most surgeons agree that in the treatment of gastric ulcer vagotomy should seldom be used because of the excellent results which follow properly performed gastric resection and the possibility of failure to remove an actual carcinoma. Vagotomy might be considered in the small group of gastric ulcer which by all evidence appear to be benign and which are situated in such proximity to the esophagus that extirpation of the lesion would require total gastrectomy. The number of such cases is extremely small for in the large majority of high lying gastric ulcers subtotal gastric resection with removal of the ulcer or local excision and gastroenterostomy can be performed. In exceptional cases of this type subtotal gastric resection without removal of the ulcer may be considered if the ulcer has all the appearance of benignity.

JAMES T. JENNINGS

THE NURSE ANESTHETIST

THE purpose of this editorial is to consider the case of the nurse anesthetist and to examine some of the factors that will influence the man without bias who must consider the matter.

The controversy. Whether or not the nurse anesthetist is a valuable adjunct to the care of the patient has been a matter of discussion for a few many years. Many will be surprised if surgery are in any disagreement

VAGOTOMY

ALTHOUGH numerous debatable issues remain regarding the exact place that vagotomy should assume in the treatment of peptic ulcer since Dragstedt and his associates focused attention on this procedure in 1943 certain aspects of the subject have become defined with a fair degree of clarity. It therefore seems appropriate that some comment be made at this time regarding what has been learned and the deficiencies in our knowledge which still exist. Many of the physiologic effects of bilateral section of the vagus nerves in man have been repeatedly demonstrated and verified. It is of more than passing interest that these observations coincide closely with those made previously in the experimental laboratory. Thus it is known that after vagotomy the neurogenic stimulation of gastric secretion is removed, the amount of nocturnal gastric secretion is reduced, emotion fails to alter the gastric mucosa, hypoglycemia does not stimulate the secretion of gastric acid,

and gastric hypomotility results. Other significant effects also have been noted. Vagotomy does not eliminate sensory stimuli from the stomach or duodenum.

The influence of vagotomy on the accessory organs of digestion has been incompletely investigated from a physiologic point of view. To date no serious deleterious effect on the function of these structures has become apparent. Certain symptoms such as diarrhea and abdominal cramps which occasionally occur after vagotomy have not been satisfactorily explained. Likewise our knowledge is incomplete concerning the physiologic effects of vagotomy on the small intestine and large bowel. A most important question which has not been answered definitely as yet is how long the effects of vagotomy persist. Certain experimental evidence (Vanzant) as well as some clinical evidence presented by Moore suggests that the effects of vagotomy may be temporary. Results of other clinical studies do not substantiate this point of view. Clarification of this important point will require further time. Various methods of dealing with the cut ends of the vagus nerves have been devised and tried in order to obviate possible regeneration and restoration of vagal continuity. Physiologic studies made several years or more after vagotomy to determine the status of vagal function should state clearly what method was employed to secure the ends of the vagus nerves.

Granted that vagotomy still is in the phase of clinical trial and that at present complete unanimity of opinion does not exist regarding the indications for this procedure, a certain amount of agreement in respect to certain points seems to prevail among those most in-

terested in the subject. Thus Grimson Colp and many others agree that thoracic vagotomy alone should not be employed as a routine operation for the treatment of duodenal ulcer. This is largely because of failure of the stomach to empty properly in a significant percentage of cases in which the thoracic approach has been used. This failure may occur even despite lack of evidence preoperatively to suggest pyloric obstruction. In addition this procedure affords no opportunity for verification of the lesion at the time of operation which in itself is not an inconsequential consideration.

In contrast, most all agree that vagotomy alone constitutes a most welcome contribution to the treatment of jejunal ulcer which occurs after gastric resection. In fact it is thought by many that this lesion constitutes the most definite indication for vagotomy today. Opinion is less well formulated on the use of vagotomy alone in the management of jejunal ulcer which follows gastroenterostomy, for under these circumstances the second phase of gastric secretion remains active.

At present most discussion revolves around abdominal vagotomy associated with gastroenterostomy as the operation of choice for duodenal ulcer. According to Dragstedt this is a most satisfactory operation; however, Walters and others have reported somewhat less brilliant results. A final decision on this subject will require the lapse of more time. At the time when end results are reported evidence also should be presented regarding the percentage of cases in which the postoperative findings suggested either complete or incomplete section of all vagal fibers. I have found it more difficult to feel confident that all vagal fibers were sectioned when an abdominal rather than thoracic approach is used. Not all surgeons share this opinion. The abdominal approach affords the obvious advantages of

permitting direct inspection of the lesion and the abdomen in general in addition to an opportunity to perform any associated surgical procedure that is indicated. Theoretically the operation which should afford the greatest chance to cure duodenal ulcer and prevent subsequent jejunal ulcer is vagotomy associated with high resection of the stomach. It seems possible that in a small group of selected cases this operation may have a certain field of usefulness.

Most surgeons agree that in the treatment of gastric ulcer vagotomy should seldom be used because of the excellent results which follow properly performed gastric resection and the possibility of failure to remove an actual carcinoma. Vagotomy might be considered in the small group of gastric ulcers which by all evidence appear to be benign and which are situated in such proximity to the esophagus that extirpation of the lesion would require total gastrectomy. The number of such cases is extremely small for in the large majority of high lying gastric ulcers subtotal gastric resection with removal of the ulcer or local excision and gastroenterostomy can be performed. In exceptional cases of this type subtotal gastric resection without removal of the ulcer may be considered if the ulcer has all the appearance of benignity.

JAMES T. PRIESTLEY

THE NURSE ANESTHETIST

THE purpose of this editorial is to consider the case of the nurse anesthetist and to examine some of the factors that will influence the man without bias who must consider the matter.

The controversy. Whether or not the nurse anesthetist is a valuable adjunct to the care of the patient has been a matter for discussion for a good many years. Many well known professors of surgery are in sharp disagreement

with the majority of physician anesthetists on this question.

The controversy has been pointed up by the recent action of the American Society of Anesthesiologists. This organization has circularized hospitals with a copy of a resolution adopted by its Board of Directors June 11, 1947. As far as the present discussion goes, the most important part of this resolution is the disapproval expressed of the training of persons other than doctors of medicine in the science and art of anesthesia in short nurses.

Quoting further from the notice sent to hospitals: This resolution has been reproduced and commented upon in the *Journal of the American Medical Association* and many State and County medical journals. In none of these has it been criticized adversely. Nevertheless, the concept contained in the resolution has, as everybody knows, been criticized strongly both in and out of print. For example, as recently as January 11, 1947, Dr. Evarts Graham¹ said: "There are some prominent anesthesiologists who would eliminate completely the nurse anesthetist. They have even supported legislation in some states which would make it illegal for a surgeon to engage the services of a nurse anesthetist. The best solution to the problem then is to encourage the training of the nurse anesthetist until there are enough physician anesthesiologists to fill the demand." We may take it that there has been widespread criticism of the policy advocated by the resolution. The policy is under discussion.

Some weak points of hospitals in utilizing nurse anesthetists. There have been a good many instances of abuse of the earning power of nurse anesthetists by hospitals. The exploitation of one department of a hospital to support the institution must be condemned.

¹Graham, E.A. J.Am.M.Ass. 947:123, 97, 99.

It is wrong in principle. There is nothing in this which says that the anesthesia department should not contribute its fair share to payment of the hospital's overhead: bookkeeping, heat, light, janitor service, etc. If the hospital buildings have been given to the institution, no rental should be charged. The well-run department of anesthesia should also retain, after all of its own expenses are paid, a reasonable percentage of its earnings for further development of the department. If the department makes money beyond these charges, its fees should be lowered for the patient's sake.

The training of nurses by nurses without real medical supervision is another fair target for the anesthesia society to shoot at.

The above are problems of administration on the professional side. The fact that the clinical limitations of the nurse anesthetist are sometimes not adequately perceived.

The nurse anesthetist unquestionably has her limitations. In the writer's opinion, her peace-time activities should in most cases be limited to the administration of ether, anesthesia and nitrous oxide-oxygen. It has been said that if she is allowed to give ether she might as well administer pentothal sodium, cyclopropane, spinal anesthesia, etc. This statement is not sound for the simple reason that ether has the greatest factor of safety of any of the commonly used major agents. When the respiration fails from overdosage of ether, the intake stops spontaneously before circulatory damage has occurred. This does not appear to be true with other agents. The hazards of the nurse administering agents other than ether are sufficiently great so that she should be limited except in unusual circumstances to this agent and nitrous oxide. She still can be extremely useful.

Some vulnerable points in the argument offered by anesthesia groups. War was a great accelerator of development of the specialty

of anesthesia. Many surgeons in military service got better anesthesia than they had previously ever had. With this and other stimuli aiding the specialty, the tendency is to pull it in the desirable direction faster than it can go. The great limiting factor here is the present shortage of trained physician anesthetists. Of all the specialists in medicine, the anesthetist seems to be scarcest. He has the greatest scarcity value. It sometimes seems as though every one of the 7000 hospitals in the United States is trying to get a physician head for its anesthesia department. This is a fine tribute to the physician anesthetist and the place he has made for himself. It is by no means to be construed as a total rejection of the nurse anesthetist.

At present, well known anesthesia training centers have waiting lists of reassured size. This is not the case over the country as a whole. Many large as well as small hospitals are already feeling the shortage of physicians for training in anesthesia.

Great numbers of physicians recently discharged from the military services have been eager for training in anesthesia, but this pressure is now much less than it was. In another couple of years men released from the A S T P and V 12 programs will no longer be available. At the same time the expansion of government facilities, as well as the civilian demand over the country is increasing. For these and other reasons it seems probable that the shortage of good men for training in anesthesia will be increasingly acute for at least several years.

Any unnecessary pressure that adds to the critical nature of this situation will win the ill will of many physicians, especially surgeons who ought to be solidly behind the anesthetist. The resolution referred to can work to the harm of the specialty and in addition by giving rise to strong opposition defeat its own ends.

With the rapid development of physician anesthesia and with the great shortage of trained personnel, it is curious that the resolution referred to should be offered at this time. It of course immediately raises the question of who at present will assume the load now carried by the nurse anesthetist if the resolution is widely accepted. The local doctor on the case? In this period of critical shortage of trained personnel, to outlaw the nurse anesthetist would inevitably mean that in great numbers of cases the surgeon would be forced to use the local doctor on the case as his anesthetist. The inadequacies of this system do not need comment. The situation is hardly solved by the attitude, "We'll use 'em but we won't train 'em."

While large medical centers can often carry out their anesthesia responsibilities largely with a very low salaried resident staff and can keep the cost actually lower than it would be if nurses were used, this raises several problems beyond the scope of the present discussion. Even though this may be the case in the large medical centers, in the outlying hospitals where the bulk of surgery is done, abolition of the nurse anesthetist requires the employment of a physician anesthetist or the use of inadequately trained staff members. Aside from the fact that the physician anesthetist is in most cases at present unobtainable by the outlying hospital, it must be recognized that if he could be obtained, the cost of medical care will thus be increased, such increase to be embarked upon only with greatest caution.

The old line large hospitals are fairly generally running large deficits. A recent editorial in the *New York Times* (September 30) calls attention to the fact that hospital deficits in the New York area are about two and one half times in 1946 what they were in 1945. It is unlikely that the average smaller hospital in the country is better off. With the costs of

It is not to be expected that medical men will take these as surprising developments, for they will be pressed upon them.

The future of the nurse with the mental and physical training emphasized undoubtedly in the future will work a great revolution, turning nurse already certified into a nurse into an anesthetist.

Legal principles. The censorship of medical practices by society action (in so far as they tend to inflexible regimentation) may have a bad long range effect upon the society when applied to widespread general practices in the care of the patient.

The use of a certifying board for coercive action by threats to remove certification in order to alter widely accepted general practice may be questioned.

There is much talk of legalistic means to force and inevitably freeze the shape of medical practice. The hazards of this have been demonstrated. Recourse to law by a medical society in order to correct what it believes to be unsound professional practices will freeze

the undesirable along with the desirable. Since the law freezes inadequately tested procedures, it will be difficult to make later needed adjustments. Surely every thoughtful physician must look with deepest reluctance on moves by the medical profession to take to the law to shape its practice. Physicians need to guide their own affairs.

The future. The nurse anesthetist is needed now; what her future position will be the writer does not know.

Let us not try the impossible. We cannot at present fill the available positions for physician anesthetists; therefore of what use are impatient attempts to hasten an evolutionary process that is already proceeding faster than we can take advantage of it?

Unquestionably a well trained physician anesthetist should head the department of anesthesia with as many physician associates as the needs of his institution require. It seems inescapable that with current shortages in this field continued training of the nurse anesthetist is at present indicated.

HENRY K. BRECHER.

THE BOOK SHELF

THE CANCER OF DESTINY

ESTHER H VINCENT Evanston, Illinois

NAPOLÉON was dropped from the womb of time on sun baked Corsica, a bare rock mass of an island its thorns and water torrents, its dark ribbons of pines thrusting themselves ambitiously up out of the Mediterranean blue. Spoil of many a war, Corsica had scowled under Ligurian Carthaginian Roman Vandal Papal, Moorish and Genoese masters before finding it self a bit of French real estate. Its fishing villages and mountain hamlets still stand like gray heaps of stone, silently indifferent to the burning suns and scorching winds of adversity. Its fishermen and goat herders its fruit and chest nut growers, are a short statured grave folk filled with dreams of grandeur based on an innate sense of equality with the great of the earth. Theirs, too is a curious heightened sensibility to the thoughts of others, an uncanny susceptibility to the shadows of future events. Theirs is a deep love of solitude, from which they derive a feeling of security of courage and fidelity. Like all primitive people they are as vain as children and they are clan

nish to the point of absurdity favoring relatives regardless of personal worth and efficiency.

The Bonaparte family was of noble Tuscan ancestry but had dwelt in Corsica since the 16th

From the Archibald Ch. rch Library North eastern University Medical School.

century. Probably little Italian influence was left by the time young Napoleon appeared although the family name was spelled Buonaparte for many a year. Father Charles Bonaparte had married a young girl of the island, Letizia Ramolino by whom he had 13 children 8 of whom lived. Tall

and vigorously beautiful Napoleon's mother was said by him to have had the mind of a man. She shared the stormy life of the Corsican rebels under Paoli and many a tale is told of her sagacity and fearlessness. Once while crossing a turbulent river her horse lost its footing and was being carried downstream. Letizia ignoring the shouted advice to jump successfully guided the frightened animal to safety. She was then carrying Napoleon in her womb. Married at 15 Letizia lived through the dramatic rise and fall of her famous child even staying with him at Elba, and finally ending her days peacefully at Rome at the age of 86.

It was from his mother that Napoleon liked to think he had inherited those qualities that made him great. But it was from

his father that he feared he had inherited the physical constitution that would destroy him. Lawyer Charles Bonaparte fought with Paoli for the liberation of Corsica. Upon the defeat of the leader he retreated with his family to the mountains only to come down again to take up the life of a parasitical

NAPOLÉON BONAPARTE
1769-1821

[illegible]

All this time Napoleon lived with the fear of cancer. He did not want to talk about it and he never mentioned his father's illness if he could avoid it, but every now and then he would disclose a queer interest in anatomy, particularly in the anatomy of the stomach. However every time he tried to learn something about it, he got sick at it. Physically squeamish, he simply could not stand the sight of the parts of a dead body. When he was Emperor he took a few private lessons from his court physician, Corvisart, but the only result was a pale, nervous, depressed Napoleon whose wife, Marie Louise, wondered why he could not eat his dinner.

Whenever conversation turned upon digestion Napoleon always vehemently asserted that he had an excellent stomach. In reality he frequently had gastric pain, and even in early youth was subject to nausea and vomiting. Sometimes he would say:

"When disease appears in the stomach a physician expends in vain, for it is the restorative center itself which is affected. The stomach is the most important part of the body."

When his last physician, the inefficient Antomarchi, suggested that the exiled emperor's stomach might be diseased, Napoleon told him to stop his nonsense, that the Napoleonic stomach was perfectly sound! Yet, a month before his death with the true nature of his illness still unknown, he suddenly began to ask another of his attendants, Dr Arnott about the anatomy and physiology of the stomach. And in dying he repeated in delirium, "The pylorus. My father. The pylorus." And finally, consciously "I have known it for a long time."

This fixed idea that he would die from cancer of the stomach saved him from fear of death in any other form. Wounded in battle, he took no heed for he knew he would not die from bullets. His belief in his charmed life in combat was not fearlessness or bravery nor faith in his miraculous in-

vulnerability but certainly that death could touch him in one way only. Upon realizing the imminence of defeat at Waterloo, he deliberately put himself in the way of bullet streams, hoping to seal his fate but to no avail.

Along with his furtive interest in gastric anatomy went an almost despairing concern in the hereditability of disease. Four of his brothers and sisters, Lucien, Elisa, Pauline, and Carolina, all suffered from stomach afflictions (eventually all 4 died of cancer or of suspected cancer). Almost privately he would ask his physicians for assurance as to the impossibility of disease inheritance. He firmly believed in it, but wanted terribly not to!

According to Dr. Paul Gosset, "The Bonapartes were a dynasty as much arthritic as imperial. Such 'slowed-down nutrition' people are frequently victims of tense agitation, spenders of reserve, with a predisposition to serious disease. Generally impatient, they gulp their food, accelerate living in general and thus promote nutritional strikes."

The schoolboy Napoleon was short and thin. Lacking good muscular co-ordination, he could not throw stones with efficiency nor ride horses without falling off of them. Too awkward to weave his hair into the elaborate male coiffure of the day he resorted to professional hairdressers, and got the habit of carrying his three-cornered hat under his arm in order not to muss his hair. His 'nervous stomach' reflected his every emotion, and vomiting followed mental upset. Never could he digest milk, nor even foods prepared with milk. His great eyes stared out of his sickly face and his voice was harshly hollow. But his living habits were simple even Spartan, and he knew how to make use of such energy as he had, just as he knew how to make use of his fellow students.

A thin bedraggled, girl-like soldier of the Revolution he earned the title of 'Little Corporal' through his magical ability to spread the contagion of courage among the men with whom he ate his coarse black bread and with whom he slept on the straw-strewn ground under the cannon. Threatened with amputation of his bayoneted leg, he ignored surgeon Hernandez, and, without rest, returned to the fray that won Toluca for his army.

As a young lieutenant at Auxonne, he presented himself as a thin yellow creature, bedridden for many weeks with what was probably the malarial fever still endemic to that region. He bombarded Blenvelot, the regimental surgeon, with questions as to the nature of his illness, and 6 months later his health was still wobbly from the infection.

At Antibes in Château-Sallé he had a serious digestive disturbance which was treated by a Dr

Desgenettes who prescribed so long a list of ineffectual remedies that he nearly undermined Napoleon's faith in the medical profession and at the same time, nearly killed him with oratory. At this time, Napoleon looked like a vagabond, with his clumsy uncertain gait, shabby clothes, and emaciated body. Stendhal states that the Napoleon of this period was the thinnest and most peculiar looking individual he had ever seen.

After the execution of Robespierre, the ensuing crisis in the Revolutionary Convention led to the appointment of Napoleon as commander in chief of the army. The feverish activities consequent upon this first step to power did not improve his health. Josephine was dismayed at his sickly looks. After their marriage, he continued to have colds and racking coughs and chest pains. Corvisart diagnosed the trouble as pulmonary congestion although he refrained from alarming Napoleon by telling him so. It is highly probable that Napoleon was suffering from an active pulmonary tuberculosis spontaneous recovery occurring later when at the close of his consulship, life grew easier for him. Corvisart's treatment of the acute attack was successful however and Napoleon was so pleased with the distinguished doctor that he made him his personal physician showering him with honors.

Napoleon's talent for judging personal worth served him well in his choice of medical men. The great Larrey was his chief military surgeon and Corvisart was not only his first physician but also his very good friend. In 1803 Corvisart had a national reputation as clinician and teacher. Among his many brilliant pupils was Laennec, father of the stethoscope. Corvisart revived Auenbrugger's art of percussion and though he did not have auscultation he was a good diagnostician. At the time of his first meeting with Napoleon, Josephine asked the physician what he thought her husband would die of. Corvisart made a snap diagnosis of heart disease. Future clinical examinations and the autopsy showed nothing abnormal with the imperial heart. It had an even though slow beat, and never gave him any anxiety. But Corvisart's guess interested him led to a discussion of aneurisms and heart disease in general, and resulted in Corvisart's writing a book on the subject and dedicating it to Napoleon. Thus there came into being one of the first books on clinical cardiology Corvisart's *Essai sur les maladies et les lésions organiques du cœur et des gros vaisseaux* (1806).

Napoleon was quick to spy out a charlatan but had the highest regard for an honest physician. Corvisart attended both Josephine and Marie

Louise in their many imaginary ills and supported the latter's somewhat psychopathic pregnancy by dosing her with bread pills to her immense satisfaction. Corvisart stood by Napoleon even after the debacle of 1814, and it was only his own ill health (apoplexy) that kept him away from St. Helena.

Science, particularly medical science, fascinated Napoleon. Although hostile to mere speculation he enthused over practical research. He was so pleased with Jenner's vaccine discovery that he intimated French experiments on smallpox and authorized a decree ordering national vaccination. One of the first French children to be vaccinated was his own little son.

The Emperor was a difficult patient, however believing in natural self regulation and saying that he preferred to die from disease than from medicine. His physicians were forced to resort to hygienic measures alone. He was peculiarly sensitive to cold kept a fire in his room even in summer and daily boiled himself in hot baths, further stimulating his sluggish circulation by strenuous massage. Horseback riding also increased his bodily heat. He slept but a few hours at a time, could sleep and awaken at will on a campaign but would awaken quickly to a strange noise or odor at home. In later life pestered by dysuria, he changed beds frequently during the night. He often fasted but, when he did eat, he ate too much and too rapidly. As time went on he experienced severe gastric pain after meals, and sometimes nausea and vomiting.

Contemplating pictures of Napoleon in characteristic pose right hand stuck in his waistcoat and left hand thrust behind his back and aware of the prevalence of scabies in the France of the Revolution many people have thought that he was always scratching himself. Whether Napoleon had the itch or whether Napoleon did not have the itch is a moot point. Stories concerning it seem chiefly legendary however. He is said to have become infected with some kind of skin ailment at Toulon after he had replaced a slain comrade at his gun. This scabby affair known as *la gale* was very prevalent among the soldiers and it tormented Bonaparte for years. As popular verse, it broke out thus

Un jour Napoléon, me prenant par la main
Cette faveur est sans égale,
Dit De moi vous aurez quelque chose demain
Le lendemain, j'avais la gale

At this period scabies was regarded as a constitutional disease. To cure it was fatal for if driven from the skin it might turn up in the vital organs and contrariwise, an infected skin might drive

disease from the organs. Thus Napoleon in Egypt is said to have been exposed to the itch in order to cure his gastric pain. Whatever he had, whether scabies or dermatitis herpetiformis or what you will, its symptoms abated under the care of Corvisart, and appeared only at intervals thereafter as a chronic pruritus, turning into what Antommarchi termed "neurotic excoriations" at St Helena.

During the years of struggle for world power Napoleon grew increasingly nervous and irritable. His temper stable enough in important matters, disintegrated into paroxysms of anger over trivial frustrations. He raged at the courier who made an inept witticism, and at the valet who made a clumsy gesture. He developed a series of tic—spasmodic shrugs of the right shoulder, mouth twitchings from left to right, tremors of the left calf. At St. Helena, the mere presence of the abhorrent Governor Lowe would set Napoleon a leg to trembling. Along with tics and nervousness went a mania for destruction. He stabbed his chair arm with a penknife, ripped his clothing and smashed the china. He cried easily over trifles. An emotional tempest would occasionally bring on a nervous fit, and he would seem to lose consciousness and fall to the floor. Lombroso thought him a psychotic epileptic, with his insolent egocentricity and his lack of moral sense. Kovalevsky the Russian psychiatrist, also considered him epileptic, as did the Spaniard, Juarros. Nevertheless, many of the characteristic symptoms of epilepsy were absent, and his physicians never mentioned epilepsy in their records, nor even in their personal correspondence.

When about 40 years old, Napoleon began to gain weight and to acquire almost female contours. From sickly yellow his complexion changed to a marbly white. From dynamic seriousness, his expression changed to dull ennui. His speech became halting and hesitant, his public addresses cold and monotonous. Even his features seemed to change. He was often tired and sleepy, suggestive of a kind of narcolepsy. This slow decline of his powers affected the turn of history. Ségur attributes the failure of the Russian campaign to Napoleon's passivity. Two days before Borodino (September 1812) Dr. Meadivier reported that he had a continuous dry cough, difficult respiration, scant and painful urination, edematous legs, and feverish pulse. Although Napoleon soon improved in health, there is no doubt but that his ailments interfered with his efficiency. At Dresden he was seized with so violent a gastric pain that he made the faulty decision that cost him the battle. Pain and weariness were with him at Leipzig (October

1813) the battle which decided the fate of the Empire. Melancholy and apprehension followed him to Paris, where in April, 1814, he signed his abdication.

His flight from Elba coincided with a sudden outburst of activity, but his "march" to Paris was that of a tired, listless man riding in a carriage. His grave somnolency was at least partly responsible for his defeat at Waterloo (June, 1815).

The jagged, gloomy rock called St. Helena is 600 miles from the nearest land, and Longwood, the seat of Napoleon's exile, is at the summit of the island's most remote mountain, cold, damp, windy, shadeless, and waterless. The governor, Sir Hudson Lowe, a wretched bully of a man, was haunted by the idea that Napoleon was trying to escape. Aggravated by his prisoner's evident antipathy, he half killed him with petty annoyances. The mortality rate of the island was very high, most of its inhabitants dying from liver complaints. Lack of fresh vegetables added misery to Napoleon's other troubles. His hitherto perfect teeth began to ache and to decay.

The British physician Dr. Barry O'Meara, was banished by Governor Lowe in 1818, partly because the doctor showed sympathy with Napoleon, and partly because he diagnosed his illness as hepatitis, the disease for which the island was notorious. With O'Meara's departure, Napoleon was freed from an endless round of calomel and purgatives. He was without medical attendance for some months, refusing to see any medical man sent him by the governor. But in January 1819, he became so ill that a visiting ship's doctor, John Stokoe, attended him without governmental authority and was court martialed as a result.

Through the efforts of the Bonaparte family Dr. Francesco Antommarchi, a young Corsican, educated at Pisa and professor of anatomy at Florence, was sent to cure for Napoleon in September 1819. Antommarchi, influenced by Governor Lowe, regarded his patient's illness as imaginary, laughed at his agony and put tartar emetic in his lemonade. Whenever Napoleon needed him, Antommarchi usually had to be summoned from Jamestown, 3½ miles away. An experienced physician would have recognized the presence of serious gastric pathology, but Antommarchi merely aggravated Napoleon's sufferings by pouring drugs into him. At last Dr. Archibald Arnott, surgeon of the 20th Regiment, was called, and had the good sense to see that the disease lay not in the liver, but in the stomach. By this time (April, 1821) Napoleon was having gastric hemorrhages and his heart action was very weak. Antommarchi's remedy was to apply a vesicatory to the

epigastric region. On the 4th of May a day of tropical storm Napoleon was in complete collapse, and at 6 o'clock the following morning he was dead.

Twenty and a half hours after death, Dr Antommarchi held the autopsy in the presence of Dr Arnott and 6 other army surgeons. Strangely enough the body was fairly fat, the heart and omenta being adipose. The abdomen was distended, the peritoneum being covered with viscous fluid. On the anterior surface of the stomach at the lesser curvature near the pylorus there was found a complete perforation now closed with adhesions. The internal surface of the stomach was practically covered by a cancerous mass, as were all of the adjacent lymph nodes. The liver and spleen were engorged and there were many adhesions between the liver and stomach. The urinary bladder contained small calculi. The left kidney was slightly displaced and congenitally (?) enlarged. Antommarchi thought he saw signs of tuberculosis in the left lung but Arnott thought the lungs normal. The brain was not dissected.

Napoleon's body had many female characteristics—small hands and feet, smooth, practically hairless skin, wide hips, and narrow shoulders. The genitalia were small and atrophied possibly due to some pituitary lesion.

Cause of death was undeniably cancer of the stomach. The state of the bladder suggested the

cause of his frequency of micturition and dysuria. Fragments of an ileum purporting to be that of Napoleon, are preserved in the Museum of the Royal College of Surgeons. These specimens show evidence of Malta fever which Napoleon could conceivably have contracted while on Elba. It is known that he had feverish attacks on St. Helena. However, the origin of the fragments is very doubtful.

At first buried in a simple, unmarked grave on his island prison in 1840 the body of Napoleon was triumphantly returned to France. And once again, that strange Napoleonic power springing from the energy of a dynamic though never healthy man roused to ecstasy the Parisian crowd which with one mighty voice proclaimed, '*Vive l'Empereur!*'

REVIEWS OF NEW BOOKS

WRITTEN from the combined experiences of a clinical neurologist, a neuropathologist, and a psychiatrist, *Neurosyphilis* by Merritt, Adams, and Solomon approaches the subject from the total standpoint. The emphasis on the progressive pathological picture, e.g. the relationship of the meningeal reactions seen early in the disease to the late picture of tabes dorsalis, general paresis, or diffuse meningovascular involvement is well placed. This relationship is unfortunately slighted in many books which describe categories as static lesions with the result that the importance of early preventive treatment of the more curable phase of the illness is missed.

The book is well documented, first with a rich clinical material available to the authors in two large American cities and second with a generous review of the literature. Many of the illustrations are related to old therapies, e.g. Swift Ellis now outmoded but the lessons are clear.

The general practitioner, not too conversant with neurological and psychiatric thinking may object to the detail of neuropathology neurophysiology psychopathology and psychiatric serology but such criticisms are easily answered. The neurosyphilist will enjoy the detailed descriptions of the meningeal lesions, the vascular lesions and the varying clinical picture. The relative incidence of these lesions is shown clearly, and differences between simulating lesions like multiple sclerosis and cerebral arteriosclerosis emphasized in the case histories. The combination of syphilis with other neurological disease, e.g. brain tumor is pointed out so that valuable weeks and months will not be lost in misdirected treatment.

The limitations of therapy in neurosyphilis may be appreciated in the clinical illustrations. Too often the medical student is taught that syphilis is treated by "specific" drugs and hence is curable. He projects this concept into neurosyphilis, forgetting that the scar of tabes or the organized thrombus in the middle cerebral artery leave irreversible defects in the neural mechanism. This book corrects such thinking but emphasizes the reversible lesions, the early meningeal involvements, the mild vascular syndromes and of course, the parenchymatous lesions of general paresis. Since many of the case illustrations are old, fever therapy does not receive the prominent place it now holds. Similarly in the light of the developments of the past 2 years, the chapter on penicillin is pitifully small and the information meager. Already a second edition is called for as the data, pre-

vously confidential for security reasons, become available for publication.

The book has the not unusual sins of a first edition, errors in grammar but these are trivial, easily corrected in a second edition.

The book, however, is a real addition and is recommended for the library of every neurologist, psychiatrist, syphilologist, and the general practitioner who encounters sizable numbers of these patients in his practice.

BENJAMIN BOONIN

HOWEVER complete, *Penicillin in Syphilis* by Moore¹ is intended only as a supplement to an earlier and larger volume, *The Modern Treatment of Syphilis* by the same author now in the third printing of the second edition. A book on penicillin in syphilis had to be written and it is well that this was done by a thorough student and a mature writer. The errors of a first edition enthusiast, both scientific and rhetorical are thus avoided. Penicillin is a potent therapeutic aid a useful one a substance which has already established itself in the medical and public eye. It has its uses and its limitations, and as use becomes more conversant with this antibiotic, its dangers too. A tremendous literature on penicillin in syphilis had accumulated because the need was great for a safer, less time-consuming, and more economical drug than bismuth or arsenic.

To collate this literature to sift it down to what was definite carefully controlled, statistically significant, required a person who was thoroughly familiar with syphilis as a disease and with penicillin as a therapeutic agent. It was fortunate therefore, that Dr. Moore elected to write this book as a supplement to his textbook on *The Modern Treatment of Syphilis*. The author recognizes that many of the facts in the book are dated that tables of dosages are being tested and revised daily that more complete evaluations of penicillin G, N, K, etc. and of even the so-called impurities are already appearing. However someone must prepare a baseline and the reviewer appreciates the historical features, the experimental data, and the basic pharmacological facts which appear in the first 8 chapters. These are the pillars on which the use of a drug is built and it was essential to document them. To prepare this rich literature collected and critically reviewed in one volume is a real contribution. Some may object to wading through this mass of material, but not the research worker or the alert clinician be he specialist or not. Some of the chapters on therapy are long others are short. These are not sins of omission, but merely the author's principle of adhering to facts.

¹PENICILLIN IN SYPHILIS. By Joseph Earle Moore, M.D. Springfield, Ill. Charles C. Thomas, 1945.

INTRODUCTION. By H. Houston Merritt, A.B., M.A. Hon. M.D., R. Wood D. Adams, M.A. M.D. and Harry C. Solomon, B.S. M.D. New York, Oxford University Press, 1946.

Penicillin is a drug which is being tested continuously in certain designated qualified places, as well as by individual research men. The validity of data is related to available material. It will take a long time to collect a statistically significant series of Erb's syphilitic spinal spastic paraplegia. There are simply too few cases therefore such a chapter is brief as yet.

The style of the book is easy and friendly. Despite numerous tables, graphs and discussions of data, the pages can be read rapidly. There is an amazing freedom from gross grammatical errors for a first edition. This reviewer found only one slip page 259 where the author lists the pupillary changes, the fifth third and second cranial nerve involvements of tabes dorsalis as cerebral. The word *cerebrum* could well be left out of paragraph 4. The legibility of the book is enhanced by a large clear type appearing on nonreflecting pages. Details stand out clearly in bold-faced type.

Penicillin in Syphilis is recommended to everyone who is interested in the antibiotic as such or in the modern treatment of this ubiquitous disease.

BENJAMIN HOGHTON

THREE new chapters have been added in the second edition of *Human Gastric Function* by Stewart Wolf and Harold G. Wolff published 4 years ago. The work extends that of Dr. Beaumont on Alexis St. Martin and of Dr. Carlson on Mr. V., and is primarily a report on the gastric functions of Tom as they were affected by drugs by mechanical stimuli, and especially by emotion. Tom at 9 years developed an esophageal stricture after drinking extremely hot clam chowder and submitted to a gastrostomy. These studies were carried on when Tom was in his fifties, and the investigators used ingenious and skillful techniques in their work.

They observed that after liquids had been introduced into the stomach there was a temporary inhibition of gastric contractions. Fluids introduced directly into the duodenum resulted in more prompt inhibition of gastric contractions but the duration of effect was the same. Many believe that this effect of fluids accounts for the relief that ulcer patients obtain when milk and alkalies are administered. Wolf and Wolff found that introduction of acid inhibited contractions. Palmer however has shown that introduction of acid accentuates ulcer pain. Possibly the inhibitory action of fluids may be lost when ulcer or inflammation of the mucous membrane is present.

Mucin content they believe important, for occasionally when acid values have been very high mucin content has been low. This has occurred during periods of serious dilemma in Tom's life. They observed that alcohol effected an increase in vascular secretion and motor activity. Smoking caused

no significant change. As for a large group of chemical agents used many were able to influence motor activity vascularity and acid secretion though the effect varied in accordance with the subject's prevailing emotional state at the time or with his affective reaction to the experimental procedure itself.

Profound alterations in gastric functions as well as in other bodily patterns were found to accompany emotional disturbances. There was depression of function if the patient withdrew from an emotionally charged situation and acceleration of function if he assumed an aggressive attitude. This influence of the emotions emphasizes again the importance of the mental outlook of a patient with ulcer and the necessity of teaching him to change his reactions to the problems of living.

There is one study of a patient with peptic ulcer before and after vagotomy. The results are valuable because of the present interest in bilateral vagotomy. Apparently the vagi are not essential to the gastric hyperemia that follows the ingestion of a meal.

Everyone interested in physiology and gastroenterology is indebted to Tom and to the authors for this scientific study and well written book.

ARTHUR J. ATKINSON

IN trying to include all of the diseases of the locomotor system as well as rheumatic fever in one volume Dr. Fletcher has undertaken a Herculean task. In *Medical Disorders of the Locomotor System Including the Rheumatic Diseases* he has an excellent approach which is to classify everything on an etiologic basis and also to take into consideration the physiologic aspect as well as the changes in anatomy. He realizes that these pioneer efforts are attended with difficult problems which will have to be solved in the future. He has deliberately given much prominence to the rheumatic diseases since he recognizes that they are a social scourge and a national problem the world over. He has devoted long chapters to the anatomy and physiology of the locomotor system, but he recognizes the lack of complete and reliable information on the physiologic side. He has obtained help from 20 contributors on different subjects. This has the advantage of making the discussions of all of these subjects authoritative and based on experience with the disadvantage that the complete unity of the book has been interrupted.

One of the best things about the book is that it is up to date and at the same time the author passes judgment on new ideas of other authors. He has a critical opinion of the ideas that have recently been advanced by some authors. He bases his opinion on the anatomy and physiology and in general he is quite sound.

The book has a thorough discussion of rheumatoid arthritis and its relation to rheumatic fever. Osteoarthritis is discussed in general, and also for specific

REVIEWS OF NEW BOOKS

WRITTEN from the combined experiences of a clinical neurologist, a neuropathologist, and a psychiatrist *Neurosyphilis* by Merritt, Adams, and Solomon approaches the subject from the total standpoint. The emphasis on the progressive pathological picture e.g. the relationship of the meningeal reactions seen early in the disease to the late picture of tabes dorsalis, general paresis, or diffuse meningovascular involvement is well placed. This relationship is unfortunately slighted in many books which describe categories as static lesions with the result that the importance of early preventive treatment of the more curable phase of the illness is missed.

The book is well documented, first with a rich clinical material available to the authors in two large American cities and second with a generous review of the literature. Many of the illustrations are related to old therapies, e.g. Swift-Ellis now outmoded but the lessons are clear.

The general practitioner, not too conversant with neurological and psychiatric thinking may object to the detail of neuropathology, neurophysiology, psychopathology and psychiatric serology but such criticisms are easily answered. The neuropsychiatrist will enjoy the detailed descriptions of the meningeal lesions, the vascular lesions and the varying clinical picture. The relative incidence of these lesions is shown clearly, and differences between simulating lesions like multiple sclerosis and cerebral arteriosclerosis emphasized in the case histories. The combination of syphilis with other neurological disease e.g. brain tumor is pointed out so that valuable weeks and months will not be lost in misdirected treatment.

The limitations of therapy in neurosyphilis may be appreciated in the clinical illustrations. Too often the medical student is taught that syphilis is treated by "specific" drugs and hence is curable. He projects this concept into neurosyphilis, forgetting that the scar of tabes or the organized thrombus in the middle cerebral artery leave irreversible defects in the neural mechanism. This book corrects such thinking but emphasizes the reversible lesions, the early meningeal involvements, the mild vascular syndromes and, of course, the parenchymatous lesions of general paresis. Since many of the case illustrations are old, fever therapy does not receive the prominent place it now holds. Similarly in the light of the developments of the past 2 years the chapter on penicillin is pitifully small and the information meager. Already a second edition is called for as the data, pre-

vously confidential for security reasons, become available for publication.

The book has the not unusual sins of a first edition, errors in grammar but these are trivia, easily corrected in a second edition.

The book however, is a real addition and is recommended for the library of every neurologist, psychiatrist, syphilologist and the general practitioner who encounters sizable numbers of these patients in his practice.

BRUCE ROSEN

HOWEVER complete, *Penicillin in Syphilis* by Moore¹ is intended only as a supplement to an earlier and larger volume, *The Modern Treatment of Syphilis* by the same author now in the third printing, of the second edition. A book on penicillin in syphilis had to be written and it is well that this was done by a thorough student and a mature writer. The errors of a first edition enthusiast, both scientific and rhetorical, are thus avoided. Penicillin is a potent therapeutic aid, a useful one, a substance which has already established itself in the medical and public eye. It has its uses and its limitations, and as one becomes more conversant with this antibiotic, it has its dangers too. A tremendous literature on penicillin in syphilis had accumulated because the need was great for a safer, less time-consuming and more economical drug than bismuth or arsenic.

To collate this literature, to sift it down to what was definitely carefully controlled statistically significant, required a person who was thoroughly familiar with syphilis as a disease and with penicillin as a therapeutic agent. It was fortunate therefore, that Dr. Moore elected to write this book as a supplement to his textbook on *The Modern Treatment of Syphilis*. The author recognizes that many of the facts in the book are dated, that tables of dosages are being tested and revised daily, that more complete evaluations of penicillin G, N, K, etc. and of even the so-called "impurities" are already appearing. However, someone must prepare a baseline and the reviewer appreciates the historical features, the experimental data, and the basic pharmacological facts which appear in the first 8 chapters. These are the pillars on which the use of a drug is built and it was essential to document them. To prepare this rich literature, collected and critically reviewed in one volume is a real contribution. Some may object to wading through this mass of material, but not the research worker or the alert clinician, be he specialist or not. Some of the chapters on therapy are long others are short. These are not sins of omission, but merely the author's principle of adhering to facts.

¹PENICILLIN IN SYPHILIS. By Joseph Earle Moore, M.D. Springfield, Ill. Charles C. Thomas, 1946.

²NEUROSYPHILIS. B. H. Merritt, M.D., A.B. Merritt, M.D., Raymond D. Adams, M.A., M.D. and Harry C. Solomon, B.S., M.D. New York: Oxford University Press, 1946.

joints. Specific arthritides and gout are taken up. There is a chapter on sciatica and one on low back pain. The various causes of low back pain are given and the author has some insight into the disturbance in function that causes low back pain. The relationship of the decompensation in function to the anatomic changes is not clear. Poor posture is still thought of as a cause of the back disturbance rather than as a symptom of decompensation. There is no distinction between the cases in which the decompensation is caused by the anatomic changes and those cases in which the anatomic changes are the result of a decompensation. He has a chapter on the foot which brings out nothing new. In addition methods of treatment are discussed particularly with regard to physical therapy and various types of injections.

It is interesting to see a medical point of view brought to a subject that ordinarily comes under the field of orthopedic surgery, and the approach is of value not only to the medical man but also to the orthopedic surgeon and to all who have to do with disturbances in locomotor function, particularly of the rheumatoid type.

EMIL D. W. HAUER.

THE monograph *Les thyroidectomies* by R. Lebovici and Gilbert Dreyfus forms a part of a series entitled *L'avenir des opéris* and is evidently intended as a refresher course in the diagnosis, management, and complications of the hyperthyroid state. It suffers the handicap of having been written on the eve of the admission of the thyroidal compounds among the agents acceptable in the treatment of hyperthyroidism which circumstance substantially reduces its value. Aside from this limitation the treatise proves to be an orderly and detailed account of a classical medical entity and a careful analysis of the complications of the disease and of its treatment. The point of view is international enough and we have references to American, English, and German authors, although no formal bibliography is included. In the main, there is little disagreement between the French and American principles of diagnosis or of treatment. We all concede that careful evaluation is desirable and that "adequate thyroidectomy" is the therapeutic ideal. It is rather in the management of the residual and the recurrent hyperthyroidism that the French surgeons appear willing to enter upon a variety of therapeutic subterfuges, such as the use of protracted ligation and of irradiation, which would receive scant approval here. It is at this point in the treatise that analysis and definition cease to illuminate and tend to become a trifle specious.

EDITH B. FARRINGTON.

THE ambiguity of the title *Chirurgie fonctionnelle gynécologique* by R. Bourc is lavishly explained in the foreword and introduction as indicative of the author's desire to do surgery and conserve function. The proposition is fair enough, but the conservation

LES THYROIDECTOMIES. By R. Lebovici and Gilbert Dreyfus. Paris: G. Doin & Co., 1928.

of function would seem too obvious a therapeutic ideal to merit such enthusiastic development.

The book consists of an outline developed to meticulous redundancy under which is described in breezy fashion everything which the gynecological surgeon could possibly do good and bad, current and obsolete. It is a fabulous bag of tricks.

EDITH B. FARRINGTON.

THE monograph *Osteotomy of the Long Bones* by Henry Milch is based upon an interesting attempt to explain the failure and success of various osteotomies on a mathematical basis. New descriptive terms are introduced for well established procedures. Impressive laboratory procedures are the polariscopic examination of plastic models under stress, the geometric study of actual bones, and the manipulation of models. Some of the diagrams are simple and will aid the reader in understanding the basic mechanical principles involved in osteotomies. Some are abstract and will tend to confuse him. Mathematicians will be interested in formulas and equations involving higher mathematics; the philosophers in statements such as "While it is true that a straight line represents the shortest distance between two fixed points, it is equally true that for any fixed length a straight line represents the longest distance between two points. If a surgeon needs a geometric excuse for cutting off a painful protruding spine of bone he is given one."

The author's previous contributions are well presented, some of them in revised form. The book has convenient record of these. The practical analysis of the various types of osteotomies is of value. The varied applications of the high femoral osteotomy though not new may be so presented as to increase their utility.

The monograph shoots over the heads of most surgeons and will touch lightly only a few of those who have specialized in orthopedics.

WALTER P. BLOUNT.

THE 19th edition of May's *Manual of Diseases of the Eye* contains 387 illustrations including 37 plates with color figures. It is still a concise practical, and systematic manual intended for the student and general practitioner.

The death of the author, Charles H. May, in 1943 deprived American medicine of a great teacher. The present edition has been revised by Dr. Peters and he is to be congratulated for adhering to the original plan of the book, editing rather than rewriting it.

This edition has been brought up to date by including considerable new material, and several color plates and drawings have been added. The new topics included are penicillin therapy, modern therapy of color vision and its anomalies, thyrotoxic and

CHIRURGIE FONCTIONNELLE GYNÉCOLOGIQUE. By R. Bourc. Paris: Masson & Co. Librairie Docteur, 1927.

OSTEOTOMY OF THE LONG BONES. By Henry Milch, M.D. Springfield, Ill.: Charles C. Thomas, 1947.

thyrotoxic exophthalmos, congenital cataract following maternal rubella and ocular brucellosis. Ocular requirements for admission to the Army, Navy Marine Corps Coast Guard and Aviation services of the United States are contained within the appendix.

May's *Manual* is one of the best textbooks on ophthalmology. It is hoped that future editions will continue to reflect the character and personality of the author.

IRVING PUNTERBERRY

THE fascinating and important field of the relationships of hormones to tumors is outlined in the symposium *Endocrinology of Neoplastic Diseases* edited by Gray H. Twombly and George T. Pack. The effect of hormones particularly the steroids in initiating and in augmenting or retarding neoplasia as well as the hormonal pictures produced by functioning tumors of the endocrine glands or by carcinomatous destruction of these glands are depicted in detail. Most of the topics discussed are still in the experimental stage and the authors have taken care to present the results of many investigators as completely as possible to evaluate this work briefly and then only to draw the most thoroughly substantiated conclusions. The defects in our knowledge are pointed out and the need of further research stressed. Such listings of results can make slow and difficult reading yet in this volume the reader is aided by the

ENDOCRINOLOGY OF NEOPLASTIC DISEASES. A Symposium by Eighteen Authors. Edited by G. H. Twombly M.D. and George T. Pack, M.D. New York: Oxford University Press, 1947

consistency and quality of the style of the different authors and by the thoughtful use of subheadings and frequent summaries. The data are timely. In some cases supplements having been added so that the latest work might be included.

Of particular interest to the clinician are the chapters on the endocrine effects of pituitary tumors by William German and on adrenal cortical tumors by Allan T. Kenyon in which the symptoms are tabulated and the mechanism for the production of each symptom postulated a rationale thus being given to the diagnosis of the unique syndromes these tumors may produce. Tumor endocrinology becomes important therapeutically in cancer of the prostate. This condition is described in detail and contrasted with the different problem presented by benign prostatic hypertrophy. The recent attempts at hormonal treatment of breast cancer are evaluated well by Ira T. Nathanson. The surgeon will be interested in the discussion of parathyroid enlargements by Oliver Cope and of pancreatic tumors by Allen O. Whipple. Attention is also given to tumors of the ovaries, the testes, the thyroid and of the pineal in this remarkably complete symposium.

These monographs will be of value to the practitioner to whom the diagnosis of hormone producing tumors is always a challenging problem to the surgeon in whose province the treatment of most of these conditions lies and to those interested in research in both endocrinology and cancer who will appreciate such a careful summary of investigations to date.

CORRESPONDENCE

ABUSE OF THE TERM SUBTOTAL GASTRECTOMY*

GASTRIC resection for duodenal ulcer has gradually replaced gastroenterostomy which used to be the operation of choice for this condition up to about 20 years ago. In gastric resection for duodenal ulcer about two thirds of the stomach should be removed. In Europe this operation is defined simply as resection of the stomach. In this country the term 'partial gastrectomy' was employed for many years and still is used by many leading clinics. Partial gastrectomy is the proper term for this type of operation. For some unknown reason many clinics in this country have adopted the wrong term 'subtotal gastrectomy' for this procedure. The unjustifiable misuse of the term 'subtotal gastrectomy' has reached such wide proportions that it seems proper to call a halt to its further abuse in connection with gastric resection for duodenal ulcer.

The term, "subtotal" implies that practically the whole organ is removed and that only a tiny rest of this organ is left behind. Thus in a properly executed subtotal thyroidectomy a minute remnant of the organ remains *in situ*.

Proc Mayo Clin 947 257

An operation analogous to this type of thyroidectomy is performed when gastric resection for a large gastric ulcer occupying most of the stomach is undertaken. After the removal of such a large gastric ulcer the stomach represents a small pouch composed mainly of part of the fundus.

These extensive gastric resections for large gastric ulcers luckily represent a very small percentage among the operative procedures on the stomach. They have one great disadvantage in their post-operative picture namely the annoyance which the small remaining stomach gives to the patient, at least during the first 6 months after the operation. Thus subtotal gastrectomy should be performed only as an operation of necessity in the presence of large gastric ulcers.

Gastric resections for duodenal ulcers which usually comprise about two-thirds of the stomach, should therefore never be classified as subtotal gastrectomies. They should be called partial gastrectomies. If every surgeon before classifying the gastric operation performed for a duodenal ulcer would remember the picture of a subtotal thyroidectomy the unjustifiable use of the term, "subtotal gastrectomy" for gastric resections for duodenal ulcers would soon be abandoned completely.

COLLECTIVE REVIEW

CARCINOMA OF THE PARATHYROID GLANDS

With a Preliminary Report of 3 Cases

EDGAR H NORRIS M.D., F.A.C.S. *Boston Massachusetts*

IN 1926 Herzheimer and in 1933 Jaffe doubted the existence of primary carcinoma of the parathyroids and even today in the minds of many the question as to whether malignant epithelial tumors arise in the parathyroid glands is debatable. On the other hand isolated reports of tumors thought to be examples of this lesion have continued to appear in the literature during the last 40 years. Indeed, malignant tumors of the parathyroids have been described (although in fewer numbers) for almost as long as have the benign tumors that arise in these glands. Certainly the enigma of the situation can be solved only by an objective analysis of all of the available, relevant information. The problem here is one of practical clinical and surgical importance as well as one of fundamental scientific interest from oncological and endocrinological points of view.

With such knowledge as we now possess the recognition of primary carcinomas of the parathyroid glands is still beset with difficulties. In the first place parathyroid cancer is undoubtedly rare and this militates against the formulation of authoritative opinion. In the second place thus far there seems to have been no attempt to define the characteristics of this particular neoplasm. This state of affairs imposes upon the problem a degree of uncomfortable uncertainty that can be overcome only by further study in the hope that a modicum of clarification may eventuate. As with any other problem, at least to a certain point the

findings will be valuable in proportion to the quantity and quality of the data used in the study perhaps the quantity and quality of available data on parathyroid cancer are too limited to permit much progress. The present study however may at least assist in defining pertinent problems. Because the data are meager no apology is made for the necessity of relying more heavily upon judgment than would be permissible in the face of more ample material it is recognized that such conclusions as are reached may or may not stand in the light of more ample material.

Our investigation has been greatly facilitated by personal observations made in the study of material from 4 cases. Since the material from 3 of these cases has not yet been reported in the literature our findings are presented following the review of the literature and these cases have been added as the last 3 in Table I.

REVIEW OF THE LITERATURE

In Table I the cases that have been reported in the literature as parathyroid carcinomas, about which more or less individualized data are given, have been assembled. In this table the cases are listed chronologically and on the basis of our opinion they have been designated as those that are almost certainly examples of parathyroid carcinoma (+) those that are doubtful (?), and those that appear to have been mistakenly regarded as examples of this tumor (o). This sorting of the cases has been done because at best the amount of material is limited, and because if a satisfactory picture of parathyroid cancer is to

From the Department of Pathology and Bacteriology, Massachusetts General Hospital, Boston, Massachusetts.

evolve, the data for each case must be adequate and convincing if they are to be accepted for use in defining the characteristics of this tumor. Subsequently the criteria employed in classifying the individual cases will be presented.

Table I includes 41 cases that have been regarded as malignant parathyroid tumors by the original essayists. Fifteen cases (Nos. 8, 9, 16, 17, 18, 19, 21, 22, 23, 25, 26, 27, 39, 40, 41) have been classified as carcinomas of the parathyroid. 3 (No. 11, 14, 20) have been classified as questionable examples, and 23 (No. 1, 2, 3, 4, 5, 6, 7, 10, 12, 13, 15, 24, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38) have been included in a group that appears to have been mistakenly regarded as parathyroid cancers. Of this last group it is interesting to note that 7 were instances reported in the year 1907, they came from a period when the general classification of tumors was being elaborated and from a time prior to the clearer delineation of the characteristics of many neoplasms. Specifically and individually 10 of the cases of this group have been omitted from the group of parathyroid cancers because for each the description given is meager or not convincing as to the parathyroid origin, or it seems to indicate a different source. Case No. 15 was called a malignant adenoma, but quite apparently it was an example of benign parathyroid adenoma. In our opinion the same is true for cases No. 28 to 38, inclusive, and more has been written regarding this latter group in the discussion.

The 3 cases assigned to the doubtful group offer greater difficulties in diagnosis but, as will be seen, there are features about each report that cause a high degree of uncertainty. In case No. 11 the diagnosis was made from a biopsy of a metastatic lesion and the supposed primary cervical tumor was never seen. In the record of case No. 14 a diagnosis of parathyroid adenoma was made of the original tumor while the histologic examination of the recurrent lesions showed wildly growing epithelial cells that produced no characteristic pattern. The report of case No. 20 includes no description of histologic structure, although 1 illustration is presented; the tumor was designated as carcinoma, grade 1, but it may have been a benign adenoma of the parathyroid. The histologic structure as illustrated and the excellent post-operative clinical result argue for the benign nature of this tumor.

There remain 15 cases that seem acceptable examples of parathyroid carcinoma, and before we enter upon a discussion of the findings in this material it will be well to review each of these 15 cases. This will be helpful for it must be admitted

that, even in this selected group, widely differing values are attached to particular cases. In the succeeding review, therefore, the cases, having been compared and weighed, are arranged according to our judgment in approximately the order of their decreasing value: those that have been most completely studied and that, for our present purposes, possess a high value are presented first. The prior position accorded the first 3 cases will certainly not be disputed; however the exact position of each of the next 9 cases is debatable. Indeed, for each of these 9 cases one would have liked to have had a fuller account; they have been accepted because they were called carcinomas, because such data as are given seem to support the claim of parathyroid origin, and because no substantial reason could be found for denying them place. The 3 cases that are being reported preliminarily are placed last in order that they may be presented as a group of new cases. The 15 cases are numbered serially in this review but to prevent confusion the serial number assigned to each case in Table I is also given in parentheses.

REVIEW OF REPORTED CASES

Case I. (No. 25.) Between the years 1939 and 1943, 4 reports were made on the case originally described by Meyer, Rodi, and Ragins in 1939 (No. 25). The prior appearance of the report and the quality and completeness of the record justify placing this case first for it is probably the most classical example of parathyroid carcinoma thus far described.

A man of 56 years came under observation complaining that for about 7 months he had suffered with a painful swelling in the proximal portion of his right little finger. He further stated that he had fractured his left humerus following a fall and that he had lost much weight in the past 6 months. In the physical examination a firm tumor the size of a walnut was palpated in the right lower part of the neck anteriorly. The blood calcium and phosphorus were 15.9 milligram per cent and 3.1 milligram per cent, respectively, and the blood phosphatase showed 22 Bodansky units. X-ray examination revealed multiple bone lesions characteristic of generalized osteitis fibrosa cystica, and renal calculi. Biopsy of the lesion in the right little finger showed the picture of osteitis fibrosa.

At operation an encapsulated tumor measuring 6 by 4 by 4.5 centimeters was removed from the right side of the neck. On section the tumor tissue was light tannish gray in color. Microscopically, the tissue was disposed in anastomosing cords and alveoli, and various cell types characteristic of the

TABLE I—CHRONOLOGICAL ARRANGEMENT OF CASES CALLED PARATHYROID CARCINOMA IN THE LITERATURE

	1907	Kocher		F	6						10x12x3	+	+				Had goiter for many years. Tumor in midline of neck.
	1907	Kocher		M	48					L—	8x7x5	+					
3	1907	Langhans		M	46						small						Had goiter for many years. Tumor near thyroid. Local recurrence. Histology suggests giant cell carcinoma of the thyroid.
4	1907	Langhans		M	48						8x7x5					+	Tumor in midline of neck.
5	1907	Langhans		M	50					L—	2x2x2		+				Histology suggests giant cell carcinoma of thyroid.
6	1907	Langhans		F	54					L—	First size						Postoperative recurrence of tumor
7	1907	Langhans		M	33						0.5	+	+				Histology suggests carcinoma of thyroid
8	1909	deQuervain	+	M	68					R—	6 g	+	+	+	+		Local recurrence of tumor. Histology seems typical of parathyroid.
9	1914	Roffo and Landivar	+	M	60					LL	very large		+	+	+		Extension of tumor into mediastinum. Histology stimulates parathyroid.
	1913	Faenzi		F	63					L—	10	+					Invasive thyroid. Histologic structure not convincing of parathyroid origin.
	1915	Ferrero and Sacerdote	?	F						R—	small mass					+	Supposed primary cervical tumor not recovered. Diagnosis made from biopsy of metastasis in temporal bone. Too indefinite to be given parathyroid origin.
	1916	Hendrick		F	7												Retracted tumor. Also tumor in upper pole of thyroid. Both tumors surrounded by thyroid tissue. Histology suggestive of giant cell carcinoma of thyroid.
13	1917	Alessandri		M	5			+								+	No cervical or primary tumor found. Diagnosis made from biopsy of lesion in bone. Too indefinite to be given parathyroid origin.
14	1919	Guy	?	F	50					LL	2x2x4			+			Local recurrence 2 months after operation. X-ray evidence of pulmonary metastasis 14 years after operation. Histology not typical of parathyroid origin.
15	1919	Wellsbeck (Wilker)		F	3	+	+	+		R—	5x3 5x3	-					Called malignant adenoma. Prompt recalcification of bones postoperatively. The patient died 1 year after removal of the parathyroid tumor. Autopsy showed an epidermoid carcinoma of the esophagus and no evidence of parathyroid tumor. (The late note on this case in paper by Alexander <i>et al.</i> , 1944.)
16	1921	Toland	+	F	60					RU	Large mass	+		+			Goiter for 8 years. Cervical mass and right lobe of thyroid removed. Death 4 months after operation from pulmonary metastases.
17	1921 1923	Bourguignon, Salmon, and Millet	+	M	35	+	+	+		LL	walnut	+					Following second operation, at which time nodule thought to be recurrent tumor was removed, the patient's symptoms improved.

INTERNATIONAL ARRANGEMENT OF CASES CALLED PARATHYROID CARCINOMA
TABLE I.—CHRONOLOGICAL ARRANGEMENT OF CASES CALLED PARATHYROID CARCINOMA
IN THE LITERATURE—Continued

Series Number	Year	Author	Carcinoma + ?	Sex	Age	Hypercalcemia	Hypophosphatemia	Renal Changes	Location of Tumor	Site of Tumor in Gland	Invasion and Metastases					Remarks
											Local Invasion	Lymph Nodes	Lungs	Liver	Bones	
18	1923	Price and Mowat	+	M	40				L.U.	Ham's egg	+		+			Following operation the tumor is cured and spread occurs through the skin. Endocrine structure characteristic of parathyroid.
	1924 1940	Hall and Chaffin	+	M	36				L—	caps	+	A	A		A?	Local recurrence 14 months after operation. Patient well in 18 months after second operation. Died 4 years after second operation. Anterior chest metastases in bones and lymph nodes. No gross evidence of tumor but areas of necrosis by x-ray were interpreted as metastases.
19	1936	Sami	?	M	47	+	+	+	RL	caps						Called carcinoma, grade I. Found and excellent postoperative improvement with recalcification of bones.
	1937	Petersen	+	M	37	+	+	+	R—	chestnut	+					Called malignant adenoma. Postoperative recalcification of bones. Tumor tissue had invaded the capsule and vein. Tumor tissue suggests parathyroid origin.
	1938	Armstrong	+	F	71				R—	ls capsule	+					By x-ray another tumor was seen in the mediastinum. Tumor is not suggestive parathyroid origin.
2	1938	McQuillen	+	F	33	—	—	—	R—	golf ball	+					Two local recurrences in 1946 following first operation. Histologic structure typical of parathyroid.
3	1939	Mackinnon		M	46				LL	supr. larynx's head	+					Although the author describes the outline of the thyroid lobes, the histology of the tumor suggests parathyroid carcinoma of thyroid.
4	1939 1940 1941 1942	Meyer, Rapson, et al.	+	M	35	+	+	+	R—	caps	+	A	A			Temporary improvement with normal blood calcium level for 1 month postoperatively. Died 2 years after operation. Recurrent tumor 3 months after operation with return of hypercalcemia. Autopsy (A) showed extensive metastatic disease and metastatic lymph nodes, lungs and kidney.
5	1939 1940 1941 1942	Meyer, Rapson, et al.	+	M	35	+	+	+	R—	caps	+	A	A			Temporary improvement with fall of blood calcium level postoperatively. Return of symptoms and hypercalcemia with recurrence of cervical tumor. Second tumor is metastatic. Involvement of lymph nodes removed and patient has remained well for 1 year; bones have recalcified.
16	94	Gracie, Blumner and Ashburn	+	M	38	+	+	+	L—	caps	+	+				Observed for only 1 month postoperatively. Histology of tumor stimulates parathyroid.
17	94	Mondala	+	F	33				L—	S	+					Good health 1 year after removal of tumor.
18	94	Alexander et al (Case 3)		M	34	+	+	+	R—	2x 2x 2x						Patient died on 17th postoperative day.
19	1944	Alexander et al (Case 4)		F	30	+	+	+	R—	2x 2x 2x						Parathyroid tumor removed.
20	1944	Alexander et al (Case 5)		F	3	+	+	+	RL	caps						

Figure 1. A chart to indicate the effect upon the serum calcium and serum phosphorus values as they were affected by the removal of the original tumor and by the development of the recurrent lesion. Chart constructed from data published by Meyer and Ragins, 1943. X=recurrent tumor discovered, D=death. O=operation

per cent and the blood phosphorus level was 1.00 milligrams per cent. On physical examination, a hard nodule about 3 centimeters in diameter was discovered in the region of the right lobe of the thyroid gland; this nodule seemed fixed to the jugular vein and carotid artery. X-ray therapy was ineffectual and the patient's condition became progressively worse until he died 3 years and 8 months after the onset of symptoms.

During these years the blood chemistry was followed up and gave the striking picture shown in Figure 1. Note the precipitous fall of blood calcium following the first operation and its gradual return to a high level with the development of the recurrent tumor.

At autopsy there was a recurrent tumor in the right side of the neck which invaded the adjacent tissues; metastatic tumors were found in the tracheal, subclavian, and perijugular lymph nodes, in the lungs, and in the right kidney; there was diffuse osteitis fibrosa cystica involving practically all the bones of the body; there was renal, parathyroid, and renal calculi were present. The microscopic findings in the recurrent tumor and metastatic lesions were the same as those of the original cervical tumor.

Case II. (No. 26). Except for the fact that it was not followed to autopsy the second case (No. 26) is most thoroughly described and certainly is of value equal to that of Case I. In 1941, Gentile and Ashburn reported the case of a man 38 years old, who came under observation because of "broken legs." For 18 months previously he

had suffered with pains in his bones; he had come slowly and progressively weaker and he lost weight. Polyuria had been present for years. Just prior to the mentioned accident a lump had appeared in the left side of his neck. The blood calcium was 14.7 and the blood phosphorus 3.1 milligrams per cent. The phenolsulfonphthalein test totaled 30 per cent after 2 hours. The Moscovitz concentration test showed the greatest specific gravity to be 1.007. The x-rays revealed fractures of both femurs and the right humerus, and a generalized demineralization of the bones.

At operation a hard, reddish brown, nodular tumor (5 by 3 by 3 cm.) was removed; the tumor was densely adherent to the thyroid. The diagnosis from the microscopic study of this tumor was adenoma of parathyroid (malignant?). Immediately after the removal of this tumor, the blood calcium fell rapidly to below the critical level; apparently tetany was prevented by the administration of calcium and viosterol. Gradually the blood calcium level returned to normal.

During the succeeding 3 months the patient's general condition and the state of the bones improved. Then his weakness and body pains returned and the blood calcium rose to a level above normal and the blood phosphorus level was lowered. The cause of this altered clinical state was not discovered until nearly 10 months after the first operation, when an enlarged cervical gland was noted in the left side of the neck. This gland was removed; microscopic examination showed metastatic involvement of a lymph node by a malignant epithelial tumor and a diagnosis of malignant adenoma of the parathyroid gland with metastasis was made.

After removal of the metastatic gland, the blood chemistry returned to normal levels. The fractures healed rapidly and some of the cystic areas of the bones became more densely filled with calcium. The case was followed up for 5 years after the first operation.¹ Following the second operation the patient's general condition again improved, his fractures healed solidly, the bones recalcified, and even the large cystic areas were nearly filled by calcium at the end of 5 years. In Figure 2 the blood calcium and blood phosphorus levels are shown as they were affected by the first and second operations.

The microscopic pathology of the tumor is so important and so well presented that the original description is quoted as follows: "Left parathyroid (the tumor) has a thick, densely fibrous capsule and trabeculae, which show patches of lymph-

¹The late follow up on this case is described in footnote in Gentile et al., (9)

NORRIS CARCINOMA OF THE PARATHYROID GLANDS

Figure 2. A chart to indicate the effect upon the serum calcium and serum phosphorus values as they were affected by the removal of the original tumor by the development of the recurrent lesion, and by the removal of the recurrent tumor. Chart constructed from data published by Gentile, Skinner and Ashburn 1941. O=operation.

ocyte and plasma cell infiltration, an occasional small area of calcification and few foreign body granulomas in which large angular spaces occur presumably cholesterol clefts. The parenchyma is formed of large and small sheets the nests and columns of cells enclosed by or embedded in the dense fibrous tissue. Tumor cells are polygonal and medium to large in size. They have much reticulogranular oxyphilic to amphophilic cytoplasm with distinct cell borders. Nuclei are medium to large in size vesicular usually centrally located commonly have one or more large nucleoli and are moderately and occasionally markedly hyperchromatic. Mitoses are present. One medium sized venous channel shows invasion of its wall by an adjacent tumor nodule. In many areas small poorly circumscribed cell nests occur and few of these show infiltration of the surrounding fibrous tissue. The larger cell sheets occasionally show focal coagulation or karyorrhectic necrosis.

Little striated muscle and less thyroid tissue is adherent to capsule.

Diagnosis Adenoma of parathyroid (malignant?)

The description of the histopathology of the recurrent cervical nodule removed at the second operation follows. The 8 by 11 mm tumor mass is enclosed in a dense layer of scar tissue which is thicker where it gives rise to trabeculae which completely or incompletely lobulate the tumor. The fibrous tissue shows patches of lymphocytes and little scattered free and phagocytosed hemo-

siderin. Parenchyma is formed of large and small sheets and strands of coherent tumor cells which are polygonal medium to large in size, and have distinct cytoplasmic margins. Cell nuclei are moderately hyperchromatic, and show one or more distinct usually large nucleoli. Few mitoses are seen. Cell cytoplasm is ample granular and oxyphilic, less often amphophilic. Tumor cells immediately surrounding blood vessels are usually larger than elsewhere and roughly columnar and show irregular radial arrangements. Few cell sheets show focal coagulation necrosis. A small collapsed cyst present in peripheral fibrous layer is lined by budlike masses of vascular granulation tissue. In some of the vascular spaces there are masses of tumor cells some apparently lying free while others are loosely adherent to wall. In some of these vessels there is little blood. Occasionally a tumor mass occurs in a larger vessel.

A small lymph node loosely attached to tumor shows moderate sinus endothelial proliferation. A second detached node shows in addition a vascular space filled with tumor cells.

Diagnosis Malignant adenoma of parathyroid gland, metastatic.

In 1934 and again in 1940 Hall and Chaffin recorded their observations in the third case (No 19) that of a man who came under their attention when 46 years of age. Five years previously he had first noted a small lump in the left side of his neck, which gradually increased in size. The patient experienced increasing difficulty in swallow

ing and breathing and he suffered frequent brief attacks of palpitation. There was no loss of weight and he had remained at his work. The principal physical finding was a moderately adherent mass, the size of an orange extending from the left side of the neck to beyond the midline. At operation this mass of liverlike tissue measuring 10 by 7.5 by 5 cm. was removed together with the left lobe of the thyroid to which it was attached. The pathologic diagnosis was adenoma of the parathyroid. (See description of the histopathology quoted in following paragraphs.) The blood chemistry had not been studied preoperatively 10 days postoperatively the blood calcium level was 9.9 milligrams per cent, and roentgenograms of the long bones gave normal findings.

About 16 months after the first operation the patient noted a small nodule immediately beneath the skin in the left side of the neck which gradually increased in size. Examination of the neck revealed the presence of 2 other smaller subcutaneous nodules. These nodules were removed and the pathologic diagnosis was recurrent carcinoma of the parathyroid.

The patient was observed for 3 years following the first operation and during this time the only incident was the local recurrence in the neck. The blood calcium and phosphorus levels were normal and roentgenograms of the skeleton showed no pathology of the bones.

Microscopic Examination (of original tumor) The mass presents the structure of a parathyroid gland. It is made up of columns and groups of small cells having faintly granular cytoplasm and relatively dark staining vesicular nuclei. These are the 'small dark chief' cells of Cowdry. Scattered among the columns are a few groups of larger 'clear chief' cells and also a few oxyphilic cells. The greater number of cell columns and groups are solid but a few are tubular or alveolar where seen on cross section. Some of these contain faintly staining homogeneous material resembling colloid. A few areas of necrosis are scattered throughout the section. Dividing the cell columns is a fine reticulum of connective tissue containing blood vessels.—**Diagnosis** Adenoma of parathyroid.

Microscopic Examination (of the recurrent lesion) Sections taken from various parts of the tumor show anastomosing cords and columns of somewhat atypical epithelial cell which in places invade the surrounding muscles, while in other parts the tumor is limited by a fibrous capsule. Here and there fairly broad bands of cellular fibrous tissue transverse the tumor. In a number of places large cell masses appear in which the

alveolar arrangement is not very evident. The nuclei of the epithelial cells are round or oval, vesicular and moderately deep staining. They contain one large and often one or two small nucleoli. The nuclei are variable in size, some of them appearing quite large. Occasional mitoses are seen. The cells are polygonal in shape and the cytoplasm is finely granular, fairly abundant, and moderately eosinophilic. Occasional small groups of cells are found in which the cytoplasm is dense. Other groups of cells which tend to be elongated or fusiform have hyperchromatic nuclei and more deeply staining cytoplasm. These cells have a loose, nondescript arrangement and appear to be distinctly atypical. When stained by Mallory's eosin-methylene blue method, these cells have eosinophilic granules in their cytoplasm while the nuclei stain a very deep blue. These are the oxyphil cells of Welch.

The small separate nodule from the right side of the neck shows invasion of the skeletal muscle.

In several places masses of tumor cells are found in the small and medium sized veins of the stroma. Other cell groups about the borders of the tumor appear to be in the lymphatic vessels.

Diagnosis Recurrent carcinoma of the parathyroid.

Toland, in 1931, reported the fourth case (No. 16) that of a woman 60 years of age who for 8 years had noted an enlargement in her neck. During the 3 months prior to coming under observation the swelling increased rapidly in size and dyspnea and dysphagia developed. At operation a large mass involving the upper pole of the right lobe of the thyroid gland was removed. The pathologic diagnosis was adenocarcinoma of the parathyroid. The patient died 4 months after the operation from pulmonary metastases. Despite the brevity of Toland's report the published illustrations of histologic structure seem convincing of the parathyroid origin of this tumor.

Roffo and Landivar recorded the fifth case (No. 9) that of a man 60 years of age who for 35 years had noted the presence of a nodule the size of a nut in the lower left side of his neck. This nodule gave no symptoms but had grown slowly to the size of an ostrich egg during the past year. The tumor was resected at operation but the patient became more and more cachectic and died 3 months after the operation. At postmortem, metastases were found in the lungs, liver and lymph nodes.

Microscopically the structure of the metastases resembled that of the primary tumor. The tumor was made up of small masses and nests of cells that in places were arranged in the form of small

follicles. The cells had polygonal outlines and definite cell walls. The general structure and the types of cells gave the picture of parathyroid tissue.

Case VI. (No 8) In 1909 de Quervain described the sixth case (No 8) which may be the earliest recorded case of a parathyroid carcinoma. The patient was a man 68 years of age, who had noted a painless swelling in the right side of his neck for 1 or 2 months. The cervical tumor measured 6.5 centimeters in diameter was removed at operation but the patient developed bronchopneumonia and died. At autopsy a tumor mass, 5 centimeters in diameter was found in the thoracic aperture. In addition, metastases were found in the cervical lymph nodes in both lungs, and in the liver.

Grossly the tumor was a round, nodular encapsulated mass. The tumor tissue was gray in color and no necrosis was seen. Microscopically of the epithelial elements were arranged in the form of irregular narrow strands. The cells were sharply outlined polygonal structures like those of the parathyroid.

Peterama (1937) recorded the seventh case (No 21) that of a man 31 years of age who had suffered for some years with body pains. Roentgenograms showed the bony changes of osteitis fibrosa. In the right side of the neck there was a firm nodule. At operation a tumor mass the size of a chestnut was removed from near the right lobe of the thyroid. After a year the condition had improved and the patient's bones showed so much recalcification that he was considered cured.

The author seems uncertain as to whether this tumor arose from the thyroid or parathyroid however the published illustrations support the parathyroid origin as do also the description of the skeletal changes and the postoperative recalcification of the bones. The author calls this tumor a malignant adenoma in his illustrations, however he shows tumor tissue in the lumen of a vein. Bourguignon and Santon (1931) and later Santon and Millot reported the eighth case (No 17) that of a man 35 years of age who had had skeletal deformities since childhood in the flat bones the disease resembled Paget's disease and in the long bones it was like von Recklinghausen's disease. When seen at the age of 35 the blood calcium level ranged from 13.7 to 15.0 milligrams per cent. The right and left inferior parathyroid glands were removed the right gland was normal but the left one was hypertrophied and weighed 211 milligrams. This large parathyroid was considered a typical adenoma. Following the operation there was no improvement in the pa-

tient's condition in fact, the osteitis fibrosa and the metastatic calcification increased.

After more than 2 years the patient was operated on again the superior glandules were not found but a hard nodule the size of a walnut was discovered on the surface of the thyroid near its left lower pole. This nodule was considered to be a recurrent lesion. In this tumor the histologic picture resembled that of the adenoma removed previously. The published illustrations of the histological findings seem convincing of the parathyroid origin of this tumor.

McQuillan in 1938 presented the ninth case (No 23) that of a woman 53 years of age who had noted a swelling in her neck for 2 years. At operation an encapsulated tumor the size of a golf ball adherent to the trachea and the right lobe of the thyroid, was found. The tumor was yellowish brown in color and had the consistency of liver. The histologic structure of the tumor resembled that of a parathyroid adenoma. It was made up of nests and cords of cells which were arranged in broad sheets in which very little stroma was present. The epithelial cells resembled those of the parathyroid.

Two years following the first operation the patient presented herself with a small, firm nodule involving the skin and subcutaneous tissue in the right side of her neck. The physical findings were otherwise negative. This nodule, which was adherent to the jugular vein, was excised. It was a ragged, nonencapsulated mass of soft yellowish gray tissue composed of large clear cells. A diagnosis of parathyroid adenoma was made with the comment that it does not appear to be highly malignant.

Despite roentgen therapy at the end of 3 months 2 more nodules appeared in the neck. At this time x ray examination of the complete skeleton gave normal findings and the blood calcium and phosphorus levels were normal.

Price and Mowat reported the tenth case (No 18) that of a man aged 49 years, who 8 years previously had noted a small lump about the size of a grape on the left side of his neck. This lump grew rapidly in the 3 months before its surgical removal. At operation an encapsulated but adherent tumor the size of a hen's egg was removed. A deep portion of the tumor that was infiltrating the wall of the carotid artery had to be left. The tumor recurred as an ulcerated fungating mass and spread over the chest and into the axilla.

Microscopic sections showed that it was made up of strands and sheets of cells resembling those of the parathyroid in places, tiny follicles were present some of these contained colloid

Armstrong in 1938 reported the eleventh case (No. 22) that of a woman 71 years of age who complained of a painless swelling which had first appeared on the right side of her neck 4 months previously. This swelling at first small had gradually increased in size. There were no other important clinical findings. The tumor measuring 11 by 11 by 4 centimeters, was removed; it was quite separate from the thyroid, but adherent to many adjacent structures. The microscopic structure resembled parathyroid tissue; there were cords and strands of epithelial cells with some tiny follicles filled with colloid. A diagnosis of carcinoma of the parathyroid was made.

By roentgenography of the chest the presence of a mediastinal tumor was identified.

Mendiola reported the twelfth case (No. 27) that of a woman, 32 years of age, who first noticed a painless swelling in the left side of her neck at the level of the thyroid. This tumor grew slowly for 8 months until it was about 5 centimeters in diameter. There were no other physical findings and the skeletal system showed no pathology.

At operation the tumor was found to be adherent to and infiltrating the adjacent muscles. Three months after the operation, which was followed by x-ray therapy, the general condition of the patient was good and there were no signs of metastases or local recurrence.

The tissue removed had no capsule and consisted of grayish white soft tissue. Microscopically it was made up of columns and nests of cells like those of the parathyroid. In some places the blood vessels had been invaded by the tumor tissue. Some small areas of necrosis were encountered.

PRELIMINARY REPORT OF 3 CASES, WITH PERSONAL OBSERVATIONS OF THE HISTOLOGY IN 4 CASES

In the files of the Department of Pathology of the Massachusetts General Hospital there are sections from 4 cases that have been sent in for study from other clinics. One of these is a section from that most significant case reported by Meyer Rosal and Ragins. The other sections are from 3 other cases, and it is planned that each of these 3 cases will be reported in full by the original observers. We have studied the histology of each of these tumors and have been privileged by the original observers, in each of the 3 new cases, to include herewith a brief preliminary statement.

Case of Meyer Rosal and Ragins Case 1 (No. 25). A single section, measuring approximately 3 by 2 centimeters on the slide, was studied. Our general findings in this tumor are in accord with the published description by the original authors, as summarized. The availability of tissue from

this well established case has been of great importance to us, for it provides a histologic criterion by which other cases may be judged. Because of the significance of this case our own histologic observations of this lesion, together with our comments, are presented in the ensuing paragraphs.

In the section the tumor appears to be completely surrounded by a false capsule of connective tissue which seems to have been formed by the agglomeration of the dense stromal bands that have been encountered by the tumor in its expansive growth. Septa of varying density arise from this pseudocapsule and divide the tumor into lobules of irregular form and variable size. In the larger lobules there is a relatively small amount of stromal connective tissue within the lobules.

It is our opinion that these relationships of the stromal and parenchymal parts hold the explanation of a very important feature in the gross and surgical pathology of this tumor. Notably in certain peripheral parts of the tumor relatively delicate cords of epithelial cells are seen infiltrating the capsular stroma; these infiltrating cords demonstrate the invasive nature of the growth, and from such histologic pictures the tendency of the lesion to be adherent can be understood. It seems probable that as time passes, these tiny peripheral cords may increase in size, by the multiplication of cells, to form the more massive lobules characteristic of the deeper portions of the tumor. However, even in the larger lobules the cells are disposed in the form of anastomosing cords or masses that vary from 1 to 4 cells in thickness, and are separated by capillaries and/or stromal connective tissue fibers.

Typically the epithelial cells are relatively large polyhedral structures with distinct cell walls. The cytoplasm is made up of fine eosinophilic or amphophilic granules, and vacuoles of variable size may be present. The nuclei are round or bluntly ovoidal, vesicular bodies that almost uniformly contain 1 or even 3 prominent nucleoli of varying size. Very few mitoses are seen.

In their initial paper (1939) Meyer Rosal and Ragins considered this tumor to be "a nonhornifying squamous cell carcinoma of the parathyroid gland; however in their later papers (1941, 1943) the thought of its squamous cell nature is no longer emphasized. From the point of view of our present effort to define the characteristics of the parathyroid carcinoma, the original diagnosis in this case is of importance. Although we can understand how the large cells and the blunt lobular arrangement suggest a squamous cell carcinoma, it is our opinion that this is not the fundamental nature of

Figure 3 Roentgenogram of skull taken prior to operation to show the marked demineralization and the cystic areas of decalcification (Case XIII)

Figure 4 Roentgenogram 4 months following operation to show the striking degree of postoperative remineralization and recalcification of cystic areas (Case XIII)

the neoplasm. A careful search failed to demonstrate convincing intercellular bridges that could not be better interpreted as artifacts or involutional changes. Certain parts of the tumor are undergoing necrosis, and granules of calcium are present in considerable numbers in both the viable and necrotic portions.

Through the courtesy of Alton R. Kilgore of San Francisco we are privileged to refer to a case operated on by him—Case XIII (No. 39). Kilgore and Taylor plan to publish a full report at a later date when more postoperative data are available. Kilgore and Taylor are to be congratulated upon the careful and thorough manner in which this case was handled, and for the study that included nearly daily postoperative determinations of blood calcium levels and a bio-assay of the tumor.

The patient, a woman 51 years of age, had noted a lump in her neck for 10 years, and had developed the classical symptoms of hyperparathyroidism (rheumatic pains, weakness, anorexia, nausea, occasional vomiting, and loss of weight) during the 2 years prior to coming for examination. Roentgen studies revealed extensive demineralization of the bones and many areas in which destructive lesions were present in the skeletal parts (Fig. 3). Multiple small calculi were also demonstrated in the right kidney. Eighteen years previously the presence of a stone had been recognized in the right kidney. A biopsy of a rib lesion

showed the picture of a giant cell tumor. The serum calcium was 18.5, phosphorus, 5.0, alkaline phosphatase, 17.8.

The diagnosis of hyperparathyroidism was made. At operation 2 tumor masses were found back of the right lobe of the thyroid, the larger of these measured about 2.5 centimeters in diameter and was removed with difficulty for it was densely adherent to the adjacent capsule of the thyroid and to the recurrent laryngeal nerve; the smaller tumor (about 1.5 by 1.0 cm.) lay behind the vessels at the lower pole of the thyroid, was not adherent, and was readily removed.

A pathologic diagnosis of malignant tumor of parathyroid origin was made.

Bio-assay of the smaller tumor raised the blood calcium of a rabbit to 19 milligrams per cent from a preinjection level of 12 milligrams.

Postoperatively the patient's serum calcium fell to a low of 7.0 milligrams per cent (without tetany) and then returned to normal. During the first 3 months after the operation the patient gained weight, lost her symptoms, and felt well. Roentgenograms of the skeleton taken 4 months after the operation showed quite marked regression of the pathological changes (Fig. 4).

*Tissues removed at operation.*¹ Microscopic sections from 6 blocks of tissue were examined. One

¹The following description and interpretation of the histopathologic findings were made by the present author and are based upon sections furnished by Dr. Kilgore.

Figure 7. Photomicrograph of an area in the tumor illustrating the lobular character of the tumor and the interlobular connective tissue septa. (X 95)

block represented a total cross section of the larger tumor. On the slide this tissue was ovoidal in outline and measured 8 by 17 centimeters. Three other blocks represented tissues from different parts of the larger and smaller tumors. The last 2 blocks apparently represented fragments of tissue removed while the larger tumor nodule was being dissected free. One of the latter blocks contained principally quiescent thyroid tissue that was being invaded by the tumor. The sixth block contained several tissues. There was a large mass of tumor tissue, on one surface of which a considerable amount of thymic tissue was being invaded by the tumor and nearby and nearly surrounded by thymic tissue, was a normal parathyroid glandule.

Histopathology of the tumor. The larger tumor was incompletely surrounded by a false capsule of connective tissue. This capsule varied in thickness and density in different places. On two opposite surfaces the capsule had been totally invaded by the tumor and from this appearance it was questionable whether the tumor could be removed completely. On one surface thyroid tissue was present in the capsule and here the follicles were being surrounded and deformed, apparently by the pressure of the encroaching tumor (Fig. 5)

and just outside the tumor capsule was a small nodule of normal thyroid parenchyma. At the opposite pole of the tumor mass, a bit of thymic tissue was incorporated within the fibrous capsule.

The fibrous tissue of this tumor was conspicuous, broad septa of dense connective tissue divided the parenchyma into masses or lobules of irregular size and form (Fig. 7). Under low power magnification these septa gave a false impression, suggesting that the tumor was constructed of sheets of epithelial cells that formed the lobules (Fig. 7). However under higher magnification it was seen that from the broad septa relatively delicate strands of very vascular connective tissue coursed through the lobules; these strands dwindled rather soon leaving only the structures of a rich capillary bed to separate the epithelial elements (Fig. 8). In places, by delicate fibrillar connective tissue, and almost everywhere, by capillaries and sinusoids, the epithelial tissue of the lobules was divided into cords and nests of cells; these epithelial cords interlaced in an irregular manner and typically they tended to be 2 cells in thickness (Figs. 8 and 9). Even in those parts where broad sheets appeared to be present careful study revealed the tendency toward the formation of

NORRIS CARCINOMA OF THE PARATHYROID GLANDS

epithelial cords. Although a few droplets of colloid were present, there was no tendency toward the formation of follicles.

The tumor had invaded adjacent thyroid and thymic tissue (Figs. 5 and 6) and showed a notable tendency to invade the blood vessels (Fig. 9).

Characteristically the epithelial cells were relatively large, polyhedral bodies that were outlined by distinct cell walls (Fig. 10). Some cells were vesicular but the majority were filled by a finely granular basophilic cytoplasm. In some areas dark cells predominated and an occasional oxyphil cell was present (Fig. 11). In certain parts the cells had departed from the more typical polyhedral form to assume columnar shapes (Fig. 12) around certain vascular spaces (Fig. 12) where they formed a pattern similar to that found in some benign adenomas of the parathyroid or at times in normal glandules. The nuclei of the tumor cells in general were round or ovoid, rather normally chromatic or somewhat hyperchromatic structures and most of them contained a prominent nucleolus. A few abnormally large nuclei were seen. Mitoses were scarce.

Through the courtesy of Monroe J. Schlesinger, Pathologist of the Beth Israel Hospital Boston

we are privileged to refer to the following case. It is planned that a full report of this case will be made by Drs. Ober and Meilman.

Case XIV (No. 40) of Ober and Meilman. The patient, a man 50 years of age complained of pain in both knees. Roentgenograms revealed cystlike destructive lesions in many bones. The serum calcium was 17 the phosphorus 2 the alkaline phosphatase 61. A tumor weighing 28 grams, was removed from the left side of the neck and the pathologic diagnosis was parathyroid adenoma. The patient's condition improved symptomatically and roentgenographically. About 1 year postoperatively the blood calcium had risen to 17 and a recurrent lesion was removed at operation. The pathologic diagnosis was carcinoma of the parathyroid. This second operation failed to correct the blood chemistry values. Four months later at the third and much more radical operation several tumor nodules were removed and the blood calcium fell from 15.8 milligrams per cent preoperatively to a low of 7.7 after the operation. Microscopic sections from each of the 3 operations were studied the comparison of these tissues was of importance for there was considerable difference between the histology of the original tumor and that of the recurrent lesions.

Fig. 1

Fig. 2

Fig. 3

Figure 1. Photomicrograph illustrating the character of the cells found in certain portions of the tumor: vesiculae dense and dark cells are present in this area. ($\times 50$)

Figure 2. Photomicrograph to illustrate a particular type of histologic pattern in which cells of columnar form are arranged around endothelial lined vascular spaces. ($\times 125$)

Figure 3. Photomicrograph of a typical area from the original tumor removed at the first operation. A mitotic figure is seen just to the left of the center of the field. The cells are disposed in the form of narrow anastomosing cords. Note the relatively small and uniform size of the cells, and the inconspicuousness of nucleoli. A moderate degree of variability in the size of nuclei is seen. ($\times 125$)

The tumor removed at the first operation had the structure of a compact parathyroid adenoma in which there was but a feeble attempt at lobulation. The polyhedral epithelial cells tended to be uniform in size; their cell bodies were filled with a finely granular eosinophilic cytoplasm in which vacuoles were rarely seen. The nuclei were round or ovoid, normally chromatic bodies, and in general most of them were of approximately the same size. Here and there, however, a moderately enlarged, hyperchromatic nucleus was found. Nucleoli were very inconspicuous and were found in relatively few cells. An occasional mitosis was seen.

Even in retrospect, except for the presence of mitoses, there was little in the histology of this lesion that could be recognized as different from what has been repeatedly seen in benign adenomas (Fig. 13).

The tumor tissues removed at the second and third operations were similar but they differed considerably from that recovered at the first operation. The lobular structure was definite; the lobules varied in size and shape and were more or less completely outlined by septa of dense connective tissue. The cords of epithelial cells were

definitely invading the walls of the blood vessels (Fig. 15) and some tumor thrombi were seen. On one surface of the tumor the parenchymal cords had grown between striated muscle fibers (probably esophageal musculature). The epithelial cells were widely variable in size; the majority had large polyhedral bodies outlined by distinct cell walls, and in these the nuclei showed a wide variability in size and considerable variation in the amount of chromatin (Fig. 14). The nuclei of these larger cells regularly contained 1 or even 3 prominent nucleoli that were variable in size. In other smaller areas the cells were not so large and tended to have small ovoid hyperchromatic nuclei.

Case XV (No. 41). Case of J. H. Young and Emerson.¹ The patient, a woman 53 years of age at the time of her operation, had been known to have had osteoporosis, with a serum calcium up to 15 milligrams per cent, for 12 years. At operation 2 tumor nodules, measuring 3.5 by 3 and 2.5 by 2 centimeters, respectively, were removed from the left side of the neck. Following the operation the patient was symptomatically improved and the serum calcium was normal for 3 years. The

¹Case from the Peter Bent Brigham Hospital.

Fig 14

Fig 15

Fig 16

Figure 14. Photomicrograph of a typical area from the recurrent tumor removed at the second operation. This figure should be compared with that shown in figure 12: the cells are larger, more loosely arranged, and more of the nuclei contain prominent nucleoli. ($\times 375$)

Figure 15. Photomicrograph of an area from the recurrent tumor removed at the third operation. Dense septal

connective tissue fills the greater part of the field. Note the invasion of this connective tissue by cords of tumor cells and the presence of tumor tissue within the lumen of a vessel. ($\times 100$)

Figure 16. Photomicrograph of an area from a benign parathyroid adenoma to show the character of the cells and the presence of huge hyperchromatic macronuclei. ($\times 375$)

serum calcium again became elevated and the patient died of renal insufficiency at the age of 59 6 years following the operation. At autopsy there was a recurrent tumor at the site of operation but no metastases were found.

The sections from this case, both those from the operative specimen and those from the lesion found at autopsy were similar. In general, the microscopic picture was so much like that described by us in the case of Meyer-Ross⁴ and Ragins, and in the case of Kilgore and Taylor that it will be unnecessary to include a description of the histology of this tumor.

ANALYSIS OF DATA (SEE TABLE II)

Sex and age distribution. The sex of the patients is recorded for all 15 cases. 8 were males and 7 were females. The age of the patient at the time he came under observation is recorded for all 15 cases. At the time of operation the patients were 31, 32, 35, 38, 46, 49, 50, 51, 53, 53, 56, 60, 60, 68, and 71 years of age respectively. Thus the youngest patient was 31 and the oldest 71 years of age. There are 4 patients in the fourth decade, 2 in the fifth, 5 in the sixth, 3 in the seventh, and 1 from the eighth decade.

Location, size and gross characteristics of the primary tumor. The tumor was situated on the right side of the neck in 7 cases and on the left side in 8 cases. In only 4 instances was the site of origin defined more specifically: in 2 of these the tumor appeared to have arisen in the left lower parathyroid, in 1 instance in the left upper parathyroid, and in the last instance in the right upper parathyroid.

In size the tumors ranged from nodules about 3 centimeters in diameter to masses measuring 11 by 11 by 4 centimeters. The majority were rather larger than smaller at the time they came under observation. Apparently the tumor tended to be ovoid or round with surfaces that were somewhat irregularly nodular. In most instances it was surrounded more or less completely by a fibrous capsule of considerable density and several times calcium deposits were noted in the capsule. A distinct tendency for the tumor to be rather firmly and densely adherent to adjacent structures was noted in nearly every instance. The sectioned surface of the tumor varied in color from tannish gray to reddish brown and the consistency of the parenchyma seems to have been much like that of normal liver.

Recognized duration and growth tendencies of the primary cervical tumor. In all but 3 cases (VIII, XIV, XV) of this series of 15 a cervical tumor had been known to exist by the patient or was discovered by the physician on physical examination. The tumor was discovered by the physician in 2 cases (I, VII) and in another case (II) the cervical swelling appeared just prior to the time the physician was consulted. In 2 cases (VI, XI) a physical swelling had been noted in the neck for about 3 and 4 months, respectively. In the remaining 7 cases (XII, IX, III, IV, X, XIII, V) the patient had known of the presence of a cervical tumor for a considerable time prior to presenting himself for physical examination—1, 5, 5, 8, 8, 10 and 35 years respectively. In all but 3 (IX, XIII) of these 7 cases, growth of the tumor was observed in the months just preceding the operation. The recent enlargement was described as gradual or slow in 3 cases (III, XII) and as rapid in 3 cases (IV, V, X).

Invasive recurrent and metastatic tendencies. In 13 cases the primary tumor showed a tendency to invade locally and was more or less firmly adherent

to adjacent structures (I, II, III, IV, VI, VII, IX, X, XI, XII, XIII, XIV, XV). In 8 cases there was a postoperative recurrence of the tumor at the original site (II, III, VI, VII, IX, X, XIV, XV). In 3 cases the tumor extended into the mediastinum (V, IX) and in one case it spread from the neck through the skin over one side of the thorax (V). The regional lymph nodes were involved in 6 cases (I, II, III, V, VI, XIII), pulmonary metastases developed in 6 cases (I, III, IV, V, VI, X) in the liver in 2 cases (V, VII) and in the kidney bones in 1 case (III). X rays suggested metastases in the bones in 1 case (III). An autopsy was done in 5 cases (I, III, V, VI, XV).

Histopathology. We have attached considerable importance to the structure of the tumor and only those cases in which the cytology and/or the parenchymal pattern strongly suggested parathyroid origin have been accepted as parathyroid carcinoma. Cells of polyhedral form with definite cell walls and cytoplasmic attributes similar to those of the variety of cells found in normal parathyroids have usually been described. In varying proportions in particular tumors, cells that may

be interpreted as dense vesicular clear dark, and oxyphil types have been noted. In general the cells of these tumors tended to be larger than the cells of normal glandules. Mitotic figures were not constant in some cases they were scarce in others numerous. One or more prominent nucleoli were commonly noted in most of the nuclei. The parenchymal elements tended to be disposed in the form of more or less closely packed cords or nests of cells, and in some instances packed follicles containing colloid were noted.

Rather characteristically the tumor mass was divided by fibrous septa into lobules of irregular size and shape the stroma, apart from the dense connective tissue septa, was usually a delicate fibrillar reticulum, or made up almost completely of capillary vessels. The infrequency of necrosis was probably due to the rich vascularity of the tumor. The invasion of the walls and lumens of the blood and lymph vessels in the capsule and septa of the tumor by tumor cells was repeatedly described. In general the recurrent and metastatic lesions showed the same histopathologic structure as the primary tumor.

Endocrine effects. In 7 cases hypercalcemia and hypophosphatemia were noted and in these same cases decalcification of the skeleton was present (I, II, VII, VIII, XIII, XIV, XV). In 2 cases renal calculi were observed (I, XIII). In more than half of the cases such symptoms as asthenia, loss of weight, polyuria, and body pains were described. The surgical removal of the tumor in the cases presenting endocrine symptoms regularly corrected the hypercalcemia, relieved the patient's general symptoms, and permitted recalcification of the bones. All of the symptoms due to hyperparathyroidism returned with the growth of a recurrent tumor and disappeared again following the extirpation of the secondary growth. It is important to note that the metastatic tissue retained the same ability to influence the metabolism of calcium as was possessed by the primary tumor.

Postoperative course. Troublesome postoperative tetany was not observed following the removal of any of these carcinomas.

In this series of 15 cases there was 1 immediate postoperative death (case VI) this patient was operated on in 1909 and died of pneumonia. In 3 cases (VIII, XI, XII) the postoperative record was too brief a period to have significance. Two patients had inoperable recurrent lesions when last seen (Cases IX, V). Three patients (cases V, IV, I) died from visceral metastases 2 and 4 months and 3 years and 8 months, respectively following the operation. In the 5 remaining cases

the results were more encouraging. The patient in case II was living and apparently well 5 years after the first operation and 4 years following the removal of the recurrent tumor. The patient in case III was living 3 years after the first operation and 13½ years following the removal of the recurrent tumor. The patient in Case XIII was living and doing well 1 year postoperatively. The one in case VII was considered cured at the end of 1 year and the patient in case XIV was living and doing well following his recent third operation at which the second recurrent lesion was removed.

DISCUSSION

There can no longer be doubt that carcinomas occasionally arise in the parathyroid glands. Unquestionably this tumor is rare, but it seems probable that more cases will be recognized in the future especially if the parathyroids are examined in all cases in which the primary malignant site is not readily observed. This point deserves particular emphasis in view of the fact that some of the tumors that have been reported were of small size, unless a careful examination of the neck is made in the clinical or postmortem study such primary lesions could be overlooked.

Apparently there is nothing peculiar regarding the age distribution of parathyroid carcinomas the distribution in the reported cases has been about that observed for other epithelial malignancies. The cases are about equally distributed between males and females.

The evidence indicates that the parathyroid carcinoma grows expansively for a considerable time and that there is a marked tendency for it to invade and to become adherent to adjacent structures even at an early period and while the tumor is yet small. General dissemination occurs through both the lymph and blood vessels masses of tumor tissue have been observed in the walls and lumens of the blood and lymph vessels, and metastases have been found most commonly in the lungs and the regional lymph nodes.

Since each of the 15 cases that we have accepted as parathyroid carcinomas was a surgical case it may not be strange that all but 3 presented a clinically recognizable mass in the neck. These 3 cases (VIII, XIV, XV) were explored surgically because of hypercalcemia, hypophosphatemia, and the associated signs of osteitis fibrosa. What is of importance in this connection is the fact that in 7 (47 per cent) of the cases the patient had been aware of a cervical nodule that had been present for an average of 10 years and a mean of 8 years before coming to operation. In 2 other instances a cervical tumor had been noted for a matter of only

a few months. This raises the interesting questions as to whether a benign parathyroid adenoma may become malignant and whether during the early period of its existence a parathyroid carcinoma is a relatively benign lesion. Neither query can be answered finally in the light of available data but there are observations that bear on both interrogations.

In the first place, approximately 95 per cent of the benign adenomas have been associated with skeletal and/or renal changes (Norris, 1947) on the other hand, skeletal and/or renal changes have been observed in only 40 per cent of the cases of parathyroid carcinoma. Perhaps this is about what might be expected for we know that about 1 or 2 per cent of the benign adenomas are nonfunctional and it certainly is not to be expected that all of the malignant tumors of an endocrine tissue would be endocrinologically active.

In the second place the average duration of a parathyroid adenoma before coming to surgery has been from 5 to 7 years (Norris, 1947) and it appears that in the cases of carcinoma a lesion had been present in the neck for at least an equal period, or perhaps longer. Although these observations do not give the answer to the questions just raised they do seem to indicate a likelihood that the benign adenoma will occasionally be found to be a precancerous lesion.

From the biological point of view certainly one of the most interesting features of parathyroid carcinoma has to do with the endocrine potentialities of the tumor. Among the 15 cases we are considering there are 7 in which endocrine effects, quite similar to those produced by benign adenomas of the glandules, were prominent in the clinical picture. In all of these there was clinical improvement following the removal of the tumor in 4 instances the clinical and metabolic betterment was halted with the development of a recurrent tumor and in 3 of these clinical improvement followed the excision of the recurrent lesion. There can be no doubt but that certain parathyroid carcinomas are functional endocrine tumors, the problem of the recognition of this tumor would be greatly simplified if we could be sure that all parathyroid cancers produced an active hormone. However the evidence is to the contrary 8 cases have been reported in which no skeletal alterations were observed and in at least 1 of these (III) there was no alteration of the blood calcium and phosphorus levels. Meyer and Ragins state "Although a number of cases have been reported, the diagnosis of carcinoma of the parathyroid gland is questionable in view of the fact that the blood

chemistry and x-ray examinations in these cases have been incomplete or failed to show the characteristic changes." If all parathyroid carcinomas are to be recognized we are of the opinion that the requirements exacted by these authors are too narrow for there seem to be well proved cases in which no evidence of endocrine activity appeared. The location and structure of the tumor are also features that must be useful criteria.

This brings us to consider these features. Although it is possible for a parathyroid tumor to develop from a glandule included in the substance of the thyroid gland the majority of this type of tumors will certainly be found outside the thyroid, but closely adjacent to it. Indeed the possibility of parathyroid origin must be kept in mind when any epithelial tumor located in the neighborhood of the thyroid is found probably the greatest difficulty will always have to do with the differentiation of tumors of thyroid and parathyroid origin. Many times this differentiation may be difficult and will depend ultimately upon the combined features of the case and particularly upon structural details.

Probably the best descriptions of the microscopic structure of a parathyroid carcinoma are those given by Gentile, Skinner and Ashburn and by Hall and Chaffin. These have been quoted in full.

Until more records of equal quality have appeared in the literature we can do no better than to employ these accounts as a yard stick by which to measure other cases. The descriptions included in these reports together with our observations on the new material reported in this paper constitute the most complete and detailed observations that have thus far been made. Possibly in the future the routine use of glycogen stains and other methods applied to all confusable lesions may be of assistance in the differential diagnosis.

In 1944 Alexander Kepler Pemberton, and Broders reported "fourteen cases of hyperparathyroidism due to formation of a tumor in the parathyroid glands" that had been observed at the Mayo Clinic. In all but 1 of their group of 14 cases a diagnosis of parathyroid carcinoma was made (Table I Series No. 15, 20, 38, 39, 30, 31, 32, 33, 34, 35, 36, 37, 38). As can be seen from Table I these 13 cases have not seemed acceptable examples of parathyroid cancer for reasons about to be enunciated in our judgment all of these cases are better interpreted as benign parathyroid adenomas.

In the first place, these authors based their diagnosis of malignancy entirely upon variability in the size of the nuclei and nuclear hyperchrom-

atism the cancerous state was recognized wholly from morphological features of the individual cells. In our opinion this criterion of malignancy alone is not adequate, especially in the case of parathyroid tumors, because varying degrees of nuclear hyperchromatism are commonly observed in the cells of normal glands and are often seen in the cells of benign adenomas (Fig 16). Wide variations in the size of nuclei including the presence of giant nuclei, have been observed in the present quarter of the reported adenomas.

In the second place these authors state 'In no case in the series under study did metastases or local recurrence occur'. Since the tumors in their series were removed at different times during the past 17 years, it would be only reasonable to expect a percentage of recurrences, metastases, and fatalities if the lesions were frank cancers, as is usual in other forms of malignant disease. Moreover, in their article one encounters descriptive statements regarding the surgical management of the tumor such as the following 'It was readily removed with its capsule. and "Removal was readily accomplished. Similar descriptions have been made frequently by many other surgeons in describing the removal of parathyroid adenomas. On the other hand, as is shown by the 15 cases of the present series local invasion, metastases, and recurrence are common, and the surgeon often encountered difficulties because of the adherent state of the tumor or its invasion of adjacent structures.

In the third place, if 92.8 per cent of the parathyroid tumors in one limited series (Alexander *et al*) are malignant, and only a maximum of about 3 per cent of all the parathyroid tumors reported in the world's literature are cancers, the difference is too great to be readily explained. Castleman and Cope took the same position regarding these cases reported from the Mayo Clinic, as that taken by the present essayist.

So much space should not be allotted to this part of the discussion if fundamental and practical problems were not involved. During the past 20 years the clinical picture of hyperparathyroidism has become well defined and magnificent surgical results have been obtained by the simple enucleation of benign adenomas. If now without the best of reasons, we were to practice wide excision, as for other malignant disease, it is doubtful if the effects would justify the altered procedure. Certainly benign parathyroid adenomas far outnumber the instances of parathyroid cancer and with such information as we now possess it seems important to distinguish clearly between the two forms of neoplasia.

Characteristically the benign adenoma is a soft, reddish brown tumor that is nonadherent and relatively easily enucleable at times it may have grown expansively around the adjacent current laryngeal nerve or some other small adjacent structure but this is different from the adhesion of invasion. Characteristically the parathyroid carcinoma is a relatively firm mass of gray tan color (the brown tones are less conspicuous than in the benign adenoma) and it is likely to be found densely and closely adherent to adjacent structures, from which it may be dissected only with difficulty. The cleavage planes tend to be obliterated by the invasive cancer. Because of these differences in the gross pathology the operating surgeon will often be enabled to make the correct diagnosis at the operating table.

It is necessary to return again to the problems of the growth tendencies and of the microscopic structural constitution of the benign and malignant lesions of the parathyroids. We have agreed that the evidence supports the thesis that a small percentage of parathyroid adenomas may become malignant. Our Case XIV is an instance in point in this case the histology of the original tumor was rather similar to that of a benign adenoma while in the recurrent lesion the microscopic picture had been altered the cells were larger and macro-nuclei and hyperchromatic nuclei were much in evidence.

Almost certainly the original tumor which was removed from Case XIV was a cancer although the microscopic pattern was not altered enough to make possible its certain recognition. Therefore we agree with the group at the Mayo Clinic who contend for the importance of macronuclei and hyperchromatic forms as features helpful in the recognition of malignancy. We do not, however agree that these features alone are sufficient to establish a diagnosis of such great importance. Such other attributes as the size of the cells, the presence or absence of abnormal nucleoli, the general architecture of the tumor and the gross pathological features referred to previously are of greater significance. All of these features must be taken into account in making a diagnosis of parathyroid malignancy.

The term malignant adenoma should be dropped in parathyroid pathology. At best it is a confusing and noncommittal term. Either a parathyroid tumor is benign in which case it should be called an adenoma, or it is malignant and should be called a carcinoma.

Finally it should be pointed out that x ray therapy appears to be ineffectual in the treatment of parathyroid carcinomas. The only effectual

Present State of the Intracapsular Cataract Operation
Arnold Knapp. *Arch Ophth.*, Chic., 1947

The author discusses the present status of the intracapsular cataract operation. Many interesting and valuable features are presented. It is pointed out that the thickest part of the capsule is in a region 3 mm. distant from the anterior pole. The thinnest part is at the exact center. The more elastic the capsule the more difficult it is for it to rupture. Following iridocyclitis the capsule thickens so that it can be more readily grasped and intra-capsular extraction performed.

The consistency of the cataract and the tensesness of the capsule also play important roles in extraction. The tensesness is greatest in swollen cataract and in hard cataract in which the nucleus lies directly under the capsule.

The primary step is subluxation of the lens by rupture of the suspensory ligament. The readiness of rupture of the zonule is proportional to the age of the patient. Generally speaking the older the patient, the easier the subluxation. In patients under 45 years of age intracapsular extraction is not easily accomplished. Because the lens can be dislodged more easily tangentially than when drawn forward side to side movements of the lens are useful in attempting subluxation with forceps.

Sclerotic lenses and soft, mature or nearly mature cortical cataracts are easiest to extract. Hard large nuclear and hypermature cataracts are less suitable for extraction and intumescent cataracts are least favorable.

Subluxation may be effected by forceps by exerting pressure on the eyeball causing the head of the lens to present or to somersault, or by suction according to Smith more reliance should be placed on pressure with the lens hook and less on traction with the forceps.

When suction is used the capsule usually ruptures if the vacuum is too great, or the apparatus slips from the cataract if the vacuum is too slight.

Accessory steps are important. They include subconjunctival injection close to the eyeball to anesthetize the ciliary ganglion, incision of the orbicularis muscle by submuscular injection of the eyelids, blocking of the seventh nerve at the stylomastoid foramen or by deep injection anterior to the condylar process, superior rectus suture incision, buttonhole incision or iridotomy, and corneal sutures.

Knapp concludes that the visual results of the intracapsular method are excellent and even better than those obtained by the extracapsular method of extraction. The chief advantages of the intracapsular procedure are the operability of the intracapsular procedure and the freedom from postoperative reaction. Although the intracapsular extraction is more difficult to perform it has been simplified and made easier by better anesthesia and by the use of sutures. Loss of vitreous is the chief danger rupture of the

capsule may present difficulties complications are difficult to deal with. Displacement of the zonulocapsular barrier which occurs in this procedure does not produce any deterioration of the eye.

JOSHUA ZUCKERMAN M D

Ocular Tuberculosis. Retinitis of Jensen (A proposed tuberculous ocular. La réinite de Jensen) G Renard. *Preser med.*, 1947 No. 33 376

Of the 4 cases of retinitis of Jensen all were seronegative for syphilis and all were roentgenologically negative for tuberculosis. Of the 3 adults one reacted positively to the cuti and tuberculin tests. Oddly enough, this patient had also an old healed lesion of the retina of the left eye in an exact symmetrical position with that in the right eye. The other patient had a strongly presumptive family history for tuberculosis. The 3 remaining patients were children who showed no evidence of tuberculosis elsewhere in the body. One responded to antisyphilitic medication (sulfarsenol) in all these patients the exudative retinal phenomena regressed leaving pigmented patches permanent. Sclerotic nodules however remained in the visual fields corresponding to the healed lesions.

The ophthalmologist sees the incipience of disease but is handicapped by the obscurity of etiology. Retinal manifestations seldom develop in the presence of active tuberculous lesions elsewhere in the body and the retina tends to react with an identical form of defense to different aggressors. Only a detailed and exhaustive consideration of clinical types and concomitant etiologic factors will permit any assurance as to the relation which exists between the lesions observed and its tuberculous origin.

Six colored reproductions depict the characteristics and progress of the lesions here cited.

JOHN W BRENNAN M D

A Case of Recurrent Aphthous Urethritis with Associated Ulcus Vulvae Acutum (Lipschuetz) A Rugg-Gunn. *Brit J Ophth* 1947 31 395

The author describes a case of recurrent aphthous urethritis with associated ulcer vulvae acutum (Lipschuetz).

This rare and recalcitrant condition is recognized as a distinct clinical entity. The symptoms of which fall into three main groups (1) periodically recurring urethritis (2) skin eruptions of various types and (3) aphthous ulcers. This type of urethritis occurs in young adults of both sexes between 20 and 30 years of age and evolves by means of relapses over a period of years. Eye symptoms appear to develop rather late in the condition but progressive deterioration and blindness usually result.

In this case which was observed over a period of 28 months dermatological symptoms were absent but the ulcer vulvae acutum of Lipschuetz was present. The patient became pregnant and went on to term. Rigo occurred on several occasions. The disease is attributed to a virus infection.

JOSHUA ZUCKERMAN M D

EAR

Total Ear Reconstruction. Preliminary Report.
Gustave Aufrecht. *Plast Reconstr Surg* 1947 3
297

The author presents a procedure based upon the existing methods for the reconstruction of a new ear. It is important to work with exactness and to build a new ear as nearly a match to the normal ear of the patient as possible. Special consideration is given to the stability, size, contour and protrusion of the ear, the depth and circumference of the concha, and other details.

A model ear of acrylic is prepared in every case. Photographs and mouldages are first made of the normal and rudimentary ears. Photographs include each profile, and front and back views. A mirror image of the mouldage of the normal ear is then made of clay or plastofin. From this the acrylic replica is prepared. It is impossible to make an exact duplicate of the normal ear by plastic surgery because of the detailed architecture of the normal ear. Therefore, we must be satisfied with a fair simulation.

In the author's opinion, the deep spacious concha is one of the most important features in creating a normal looking ear and, even if it is impossible to duplicate the delicate contour of the normal ear with the proper depth of the concha the average observer can not greatly notice the lack of finer contours in the reconstructed ear.

Instead of a shell for reconstructive purposes, the pinna is considered as a massive, semicircular body which provides a broad base and assures stability. In the center is a hole, which is the concha. The base of the concha should not contain cartilage and this enhances the depth and aids in the stability of the new ear. The thickness of the cartilage block, which is at a right angle to the skull, varies according to the protrusion of the ear.

In order to provide such a cartilage block, the author has employed two different procedures. One is to prepare a mold in the form of an acrylic case made in accordance with the revision of the mirror model of the normal ear. In making this, allowance must be made for the thickness of the skin in preparing the mold. The inner surface of the case represents

the negative form of the ear cartilage. Many perforations are made in the wall of the mold to allow for adequate blood supply. Sufficient rib cartilage cut up in small chips and thin platelets is put into the case and the cover is secured over it. The entire thing is buried under the skin of the chest and left buried for at least 6 months and kept necessary.

In the other procedure two or three rib cartilages from several of the ribs are pieced together and the broad surfaces are planed down to fit each other. They are tied together with stainless steel wire or silk and transplanted under the skin of the chest for a period of at least 4 months, during which time a fairly firm fibrous capsule develops about it. With either method the following steps are generally the same.

A postauricular flap is prepared and one must be sure to have a larger flap than is thought necessary as a large amount of skin is required to cover the surface of an ear. In spite of a large flap, some additional skin often has to be provided for the lining of the concha, for the helix and the cranial surface of the ear.

The large skin-scalp flap is prepared with a crescent shaped incision and the skin is elevated to a carefully established line, corresponding with the anterior edge of the ear. The flap should be delayed once and may have to be raised in two sections.

If a rudimentary ear is present it should not be discarded but saved so that it can be utilized later.

After the blood supply of the flap is assured, the molded cartilage ear or cartilage block is transplanted under it and accuracy at this point cannot be over emphasized. As much care should be taken as possible to make it correspond with the normal ear, although unfortunately a marked facial asymmetry and other congenital defects may make it difficult. The cartilaginous ear is carefully anchored in its proper location with sutures and the hole representing the concha has to be carved out from the cartilage, if not already prepared. This will allow the skin flap to follow the depths of the concha and will also allow the rudimentary ear cartilage bundle to remain in place temporarily. The blood supply of the flap is carefully guarded and a Thiersch graft is used to cover the skin flap defect temporarily.

In about 4 to 6 weeks the concha is prepared and with an incision, according to the configuration of the rudimentary ear its cartilaginous elements are removed and the skin covering is inverted to form the lining of the new concha. The dimensions of the concha must be exaggerated to allow for the thickness of the skin, scar formation, and contracture and usually additional skin grafting is necessary. Pressure over the skin graft is employed by packing tape and the first dressing is carried out after 12 or 14 days and the concha repacked with gauze for an additional few weeks to counteract any tendency to contracture.

Four to 6 weeks later the cranial surface of the ear is prepared. The cranial surface is now carved so

Fig. 2. Mouldages of normal and rudimentary ears. In the center acrylic mirror model of normal ear.

SURGERY OF THE HEAD AND NECK

25

According to the acrylic ear but it should not be deep lest the stability of the new ear be jeopardized. The denuded cranial surface of the ear and the skin defect on the mastoid area are covered with a one-piece graft covering the scalp is excised and the skin edges approximated. After the back of the ear is lined, the ear lobe is attached to the new pinna. If the ear lobe is narrower than that of the normal side, it can be enlarged by unfolding a flap from the posterior surface of the lobe. The defect is lined by the end of the skin tube used for the helix.

Part of the new pinna is usually covered with hairy scalp and the hair can be removed either by electrolysis or surgical resection of the follicles. Now only the attachment of the new helix remains. A clavicular skin tube has been prepared and step by step moved up to the ear. These are then attached in the proper position.

There are many small details and anesthetic requirements in reconstructive surgery which the surgeon must solve according to their presentation.

WILLIAM A. ARNOOD M.D.

Deafness Tinnitus Vertigo and Neuralgia of the J Goodfriend Arch. Otol., Chic. 1947 46 1

Deafness tinnitus vertigo and neuralgia of the lateral facial region are present to some degree in 10 per cent of the population. Many of these are caused by disturbances of joint relationships in the temporomandibular joint. This articular pathology is caused by malposition of the condyle in the relation of the mandible and its condyle is erosion of the articular bone surfaces fibrocartilagenous articular cartilage and degeneration of the mandibular joint and the common wall between the ear and outer ear canal. This dividing wall consists of connective tissue, cartilage and bone which is intimately related to joint and ear structures and lodges and transmits important nerves arteries veins, membranes ligaments and muscles. Over closed traumatic, or maloccluded articulations of the natural or artificial teeth are at fault. Treatment consists of establishing normal joint relationships by replacement rehabilitation or regulation of the teeth.

Three case histories are reported. In cases 1 and 2 patients suffering from severe attacks of vertigo were markedly improved by correcting overclosure of the dental bite and in case 3 the patient was relieved of "chronic tinnitus" in the same manner. Chronic tinnitus is not curable by treatment of the dental bite but often is made more bearable. In cases of progressive deafness hearing cannot be improved but its progress can be slowed. Early deafness, if caused by abnormalities of the dental bite can be cured by proper dental treatment.

JOHN R. LINDSEY M.D.

Rupture of the Tympanic Membrane of Blast Origin F Boyce Korkis J Lar Otol Lond, 1947 61 367

This is a review of 167 cases of acoustic trauma of which 123 or 73.6 per cent, were unilateral and 44 or 26.3 per cent, were bilateral with a total of 111 ruptured drums 57 in the right and 66 in the left ear in the unilateral cases. Cases examined within 1 week comprised 58 per cent in the second week 21 per cent and after a fortnight 21 per cent. The cases considered all presented normal hearing prior to exposure.

High explosives as shells mines and aerial bombs were the most frequent causes of the blast wave. The high incidence of bilateral rupture was caused by booby traps. Explosion in a confined area is more liable to cause bilateral rupture. Unilateral rupture is commonly brought about by a blast wave on the same side as the lesion. A closed or open mouth and the eustachian tube had little influence on the mechanism of rupture but the important factor was the relation of the axis of the external canal to the source of the blast wave. As ear protectors were used by only 2 patients in the series and they also suffered unilateral rupture such protectors are not considered in this work.

The first otological symptom is one of deafness and tinnitus and very infrequently pain during the moment of rupture. Jones-Phillips analyzed 200 cases in the First World War and found the symptoms in order of frequency to be as follows deafness, tinnitus vertigo pain and bleeding. These differed from those of the present series in that headache took the place of pain. Otitis media followed in 47.9 per cent of the cases as compared to 56 per cent as reported by Craig 23 per cent reported by Collins and 34.6 per cent reported by Lundman. Interference such as the applying of drops or syringing increased the incidence of infection. The majority of cases of otitis media occurred within 4 days after injury a surprising number within 24 hours and 1 case as late as after 6 months. Among the predisposing factors are acute nasopharyngeal infection late administration of ear drops syringing or accidental entry of water into the ear and forcible nose blowing. Hospitalization is advocated.

The average time for healing in the cases complicated by otitis media was 38 days and in those without infection 20.4 days. The average total duration of otorrhea was 21.5 days. The shortest time required for healing in the infected group was 15 days and the longest 85 days while in the uninfected series these time periods were 9 and 69 days respectively. In both groups the commonest period of healing was during the third week and in the majority of cases between the third and fifth weeks. Small perforations infected or uninfected healed faster than the medium and large perforations. The most common shapes of perforations are the reniform oval and round varieties always involving the pars tensa (never the pars flaccida) and usually its lower half. In typical uninfected perforation the

membrane appears to be punched out with a clean cut edge and it is very seldom everted. During the period of healing the edges of the perforation become red and thick, and concentric rings of tissue alter its size and shape until the tympanic membrane appears to be normal or the scar becomes permanently visible with retraction.

Functional examination of the ear by whisper and conversational voice tests, tuning forks, and the audiometer showed a minor degree of deafness in 37 per cent, a moderate degree in 48 per cent and a severe degree in 15 per cent. The author found the Rinne and Weber tests fallacious in determining the type of deafness. Recovery of hearing for low tones appears to precede that for high tones and in mixed deafness a high tone loss persists. Illustrative audiograms are given.

A. B. VICKARIO, M.D.

Closure of Perforations of the Tympanic Membrane. Albert M. Dunlap and Harold F. Schuknecht. *Laryngoscope*, 947 57 479.

The authors report a series of cases of closure of the tympanic membrane by the use of trichloroacetic acid cautery. This method is not new having first been tried by Okuniff in 1895, and again used in 1917 by Dunlap reporting from China.

The authors also mention other methods that have been tried to close perforations of the ear drum, including small skin grafts, egg skin, wax, paraffin oil soaked into a cotton ball, cadaver stapes, Cargile's membrane and gold dental cylinders. The more recent work on artificial membranes has been reported by Niskell and Stefmann, both of whom use cellophane.

Some definite benefits can be derived from permanent closure of drum defects: (1) there is often relief from repeated ear infections in those previously subject to them; (2) in some cases there is an increase in auditory acuity and in interpretation of the source of sound; (3) closure of a drum defect is an aid to applicants to specialized military and civilian training schools, who previously could not meet the requirements; (4) occasionally there is relief of troublesome tinnitus; (5) after a drum has been repaired, patients can return to aquatic sports without fear of otitis media.

The authors' method is not a new one. It consists of repeated applications of a small amount of saturated solution of trichloroacetic acid to the margin of a drum perforation. It is necessary to apply a local anesthetic to the edge of the drum first, and a good anesthetic agent consists of equal amounts of menthol, phenol, and cocaine. After application of the anesthetic the margins are wiped dry so that the acid will not be diluted and run on to the adjacent drum membrane.

A small copper or silver wire bent into a loop at one end for a handle is dipped into the acid and carefully applied to the entire margin. Where the acid touches the drum, a white eschar appears and one can see how completely the margin has been treated. Applications are made at weekly intervals until a

good granulating margin has been obtained. This may require weeks or months. Unlimited patients must be had on the part of both patient and doctor.

The use of two or three drops of saturated solution of urea once or twice a day will incite an inflammatory response and may aid in the closure.

Formation of an exudate along the margin is evidence that activity is present. Any dried exudates are removed once or twice a month. If necessary Closure is slow until the entire margin is active and inactive segments of the margin fail to show a line when touched with a cotton tipped applicator. When the entire margin becomes active, cauterizations should be less frequent, but the urea drops should be continued.

With this procedure a period of from 6 months to 1 year is required for closure, depending upon: (1) size of the perforation, (2) occurrence of intervening attacks of otitis media, (3) character of drum response, (4) age of the patient and (5) the skill and perseverance of the operator. The results are better in the younger patient, although patients over 50 years of age have been successfully treated.

Contraindications to attempting closure of a drum perforation are: (1) any form of mastoid disease; (2) the presence or suspicion of cholesteatoma of the middle ear; (3) destruction of the ossicular chain in some cases; (4) continuously discharging ear; (5) complete loss of pars tensa; (6) large marginal perforations; (7) obstruction of the eustachian tube.

The authors discuss the histopathology of perforations of the ear drum. They state that repair of a drum perforation stops when more hardy, rapidly growing stratified squamous epithelium of the external surface of the drum grows over the edge of the perforation and meets the pseudostratified columnar or cuboidal mucous membrane of the middle ear. Destruction of the perforation margin with acid removes this epithelial barrier and incites, by tissue destruction, an inflammatory healing response in the drum margin. Proliferation in the middle layer of the drum is responsible for the laying down of new tissue, and regeneration of the drum begins. Frequently after the drum has healed it is difficult to tell the new part of the drum from the old.

The authors show several photomicrographs of the histopathology of a perforation of the ear drum and also in diaphragmatic form, show the type of perforations that they have successfully closed. A few representative case histories are given.

WILLIAM A. ANDERSON, M.D.

Tests for Labyrinth Function following Streptomycin Therapy. Aram Glorig and Edmund Prince Fowler. *J. Am. Otol. Rhinol.*, 947 56 379.

Vestibular and audiometric tests were performed in 38 cases of pulmonary tuberculosis before, during, and after streptomycin treatment. Of 23 patients who had had more than 3 months of streptomycin therapy all but 1 patient maintained a normal audiogram. Almost all patients had vestibular disturbances. Slight nystagmus on lateral gaze and

blurred vision while reading frequently occurs before changes in vestibular function are noted. In most cases vertigo occurs in from the twentieth to twenty fifth day of treatment. After turning the head or body the patient has the sensation of continuing to turn later there is vertigo only on sudden movement. The caloric test used was a slight modification of the method of Fitzgerald Cawthorne and Hallpike. By carefully controlling water temperature it was noted that responses to water at 30° C and 44° C were approximately equal.

In 35 cases the nystagmus times were first shortened by 30 seconds or more on the twentieth to the twenty fifth day of treatment. In 30 cases the patient gave no response after periods of time varying from 30 to 67 days. All persons whose gait could be tested walked with a broad base and some ataxia, which began in from the third to fourth week. Compensation was gradual and at 4 months incapacity was not perceptible if vision was unobstructed and the walking surface smooth. Difficulty was experienced when walking on a rough surface or in dark, unfamiliar surroundings. Rotation produced no reaction and galvanic tests showed decreased response in the patients tested. There has been no recovery up to 4 months subsequent to the first negative caloric response. Eight patients in another series have shown no recovery after 1 year. Tilt table reactions have delayed jerky and inadequate adjustment reactions suggestive of a peripheral lesion. The lesion in these cases is probably in the labyrinth however thus far no supportive micropathology has been found in the specimens studied. Sound location was normal in the cases studied which refutes the idea that this function resides in the vestibular apparatus.

NOSE AND SINUSES

Penicillin Therapy in Chronic Suppurative Sinusitis. A Report of 23 Cases. Harold Boyd, Laryngoscope 1947 57 400.

The author presents the results of his experience with penicillin to the treatment of 23 patients with chronic suppurative disease of one or more paranasal sinuses. Both the subjective and the objective findings indicate that chronic suppurative sinusitis does improve with penicillin therapy. Numerous reports from the literature (from late in 1942) on the treatment of sinusitis with penicillin are reviewed. The different procedures in which penicillin was used are discussed and some reports by other authors are briefly presented in which it is recognized that acute disease of the ears, nose and throat responds readily to penicillin however only a few favorable reports of its use in the treatment of chronic sinus disease have appeared. The author states that penicillin therapy preoperatively and postoperatively in surgery for chronic sinus disease has given excellent results. The cases reported include all patients with chronic suppurative sinusitis who were admitted to an Army

General Hospital in the United States from October 1944 to February 1946. All cases of acute sinusitis or subacute sinusitis were omitted. The majority of the patients had been given previous treatment surgery in some cases and therefore the possibility of improvement by conservative treatment seemed questionable.

In general, all cases were dealt with as follows: A careful history was taken and a clinical examination of the ears, nose and throat was carried out and all findings recorded. Roentgenograms were taken and cultures made of the pus from the sinuses, although it was impossible to make cultures of anaerobic organisms.

The patients were seen in the ear, nose and throat clinic every 2 days and, when necessary, the nasal mucosa was shrunk down by topical application of a 1 per cent cocaine solution and 35 per cent neosynephrine. Free pus was removed by gentle suction. The affected maxillary sinuses were then lavaged with normal saline solution until the return flow was clear. A needle was introduced into the antrum through the inferior meatus and with the needle still in place penicillin solution containing 250 units per cubic centimeter was instilled until there was a copious return flow from the nose. Careful notes of improvement as the result of treatment were taken at each visit, as well as the amount and character of the pus removed. At the same time the patient was given intramuscular injections of penicillin 30,000 units every 4 hours for six doses daily. As a rule, sinus irrigations were discontinued after the second negative lavage but systemic penicillin was continued for a longer period, usually for 14 days. If the nasal mucosa did not resume a normal appearance penicillin was continued longer. At the time when all penicillin was discontinued, sterile saline was instilled into the sinus and after 5 minutes a sample was withdrawn and sent to the laboratory for final culture studies.

Not only initial x-ray examinations were taken but, in addition, follow up x-ray examinations were made at intervals irregularly at first but later as soon as the sinuses were clinically clear and at least once again before the patient was discharged. When the patient was clinically symptom free he was usually sent on a 30 day convalescent furlough and upon his return a careful interim history was obtained and a further clinical study carried out and recorded. Additional sinus cultures were also taken at that time.

Although intensive local therapy other than that mentioned above was not used in the cases reported sound surgical principles of drainage were not neglected. In one case a submucous resection had to be done and in another case a nasal polyp was removed. Infraction of the middle turbinate was done routinely in all cases with questionable drainage due to edema and swelling in the middle meatus. The average age of the patients treated was 27½ years. Each patient was incapacitated for further useful service in the Army because of chronic sinus.

itis. The duration of symptoms varied from 8 weeks to approximately 10 years. The author presents in some detail the type of sinusitis shown in each of the 22 cases and the previous treatment which they had received. Included is a table of the types of sinusitis treated. Four of the 22 patients showed some allergic manifestations and the author states that in these patients there was no return to normal after clearing of the infection because of the allergic condition. The organisms isolated from the different cases are mentioned.

Nineteen of the 22 patients stated that they felt well at the end of the follow-up period, which speaks well for the treatment that they received. Three patients were not entirely well and one of these had a definite nasal allergy and his only complaint was occasional sneezing. Another patient felt improved but complained of mild, persistent headache. This patient was discharged from the Army for other reasons before a sufficient period of observation. The third unimproved patient had persistent headaches and objectively he had profound improvement in his sinusitis. His headaches were thought to have a neuropsychiatric basis.

Further analysis of the results showed that in 21 cases suppuration from the nose and sinuses cleared up entirely as far as could be determined clinically in the remaining case there was slight crusting over an atrophic middle turbinate, a result of previous surgery.

In 5 patients nasal stuffiness persisted to some degree. In 4 of these the condition was one of proven or suspected allergy. The fifth patient was entirely free of symptoms except for periodical nasal stuffiness.

The appearance of the nasal mucosa returned to within normal limits in all but 5 patients. Four of these had an allergic rhinitis, and 1 had a mild atrophy of the middle turbinate.

In general, the improvement shown in x-rays of the sinuses was considerably less than one would expect from the favorable clinical results. However, the clinical improvement was usually accompanied by corresponding improvement in transillumination, regardless of the x-ray appearance.

WILLIAM A. ARROGG, M.D.

Rubber Catheter used to Maintain the Patency of the Ostium to Dacryocystorhinostomy; a Preliminary Report. Joseph L. Goldman. *Arch. Otolaryng. Chlc.*, 1947 46 58.

The author gives a brief résumé of the operative treatment of chronic dacryocystitis by either the external or intranasal approach. In general, the ophthalmologists have favored the external, while the rhinologists have favored the intranasal procedure with some exceptions such as the modified Toti external operation by Mosher and the intranasal dacryocystorhinostomy of Wiener and Sauer a modification of the West technique.

This is a report of 4 cases in the armed forces in which there was obstruction of the lacrimal system.

In 3 intranasal dacryocystorhinostomy (Wiener-Sauer) was performed and in the fourth one an external operation (Toti Mosher) was done. The intranasal operation in brief, was as follows.

The posterior portion of the lacrimal bone containing the lacrimal sac was localized by passing a Ziegler probe into the sac and through the lacrimal bone into the nose always with traversing of a part of the anterior ethmoid labyrinth. The anterior tip of the middle turbinate was removed and the anterior ethmoid cells exenterated. With a small gouge and ethmoid punch forceps, the lacrimal bone was removed followed by excision of the adjoining thickened wall of the lacrimal sac with a No. 11 Bard Parker blade. A lacrimal syringe needle was inserted into the sac to outline its limits. After the creation of the ostium, a black silk thread was passed through the inferior canaliculus into the nose and the eye end of a straight needle and this lower end of the thread in the nose was sutured to the end of a rubber catheter No. 12 or 14 and then the catheter was pulled into the sac. A strip of adhesive tape on the forehead anchored the upper end of the thread to hold the catheter in position. Bleeding was controlled during the operation and no packing was used. A submucous resection of the septum was done to obtain adequate exposure of the lacrimal area.

In the fourth case, because of the absence of the lacrimal sac, the Toti Mosher technique was employed except that the nasal mucous membrane and the sac were not sutured together but, instead, a No. 10 catheter was inserted into the fundus in the same manner as in the intranasal operation of the aforementioned 3 cases. A preliminary submucous resection, with removal of the anterior tip of the middle turbinate and anterior ethmoid cells, was also done on this patient.

In 2 patients it was necessary to remove the catheter and thread on the seventh day because of a local inflammatory reaction in the canaliculus and adjoining portion of the sac. In the other 2 patients there was no local reaction. 1 received sulfadiazine for 8 days and the other penicillin for 14 days, post-operatively and the catheter and thread were removed on the fourteenth day. It is believed that penicillin should be the drug of choice for this purpose. Merbromin and fluorescein were used to test the patency of the ducts. The patients were observed for the following periods: 2 years and 2 months, 3 months, 4 months, and 5 months. Direct contact was lost with the first 3 patients because of transfer to other installations, but they were advised to write the author for any evidence of closing of the ostium and such information has not been received.

Estlander Abbe Operation to Treating Secondary Hardlip Deformities and Defects of the Upper Lip Resulting from Cancer. Varnstedt H. Krasnjian. *Plast. Reconstr. Surg.* 1947 3 307.

The author describes the treatment of secondary defects in cleft palate patients and the principal types

of deformities. These deformities are not apparent at first but as the child grows older they become more conspicuous. Special attention is called to the under development of the upper jaw and the upper lip and the overdevelopment of the lower lip to compensate for the defect of the upper

The general principles of treatment are outlined and it is recommended that the construction of an adequate framework in the form of a dental appliance be carried out to act as a support to the upper lip in addition to the Eastlander Abbe operation. The procedure of this operation is described in detail and the article is illustrated with 30 photographs.

Temporomandibular Joint Arthritis and Its Treatment by Extirpation of the Disc. Karl Boman
Acta chir scand 1947 95 Supp 118

The most common cause of injury to the temporomandibular joints is malocclusion of the teeth. Direct trauma to the mandible and inflammation in and around the joint will precipitate symptoms in some cases. The common local symptoms are crepitation snapping limitation of motion and pain in the joint. Peripheral symptoms of headache referred pain to various areas of the head and dizziness may occur. The literature is reviewed on the question of the effect of malocclusion on eustachian tube function.

In a survey of healthy adults more than one third were found to have a history of having had snapping mandibular joint. In exceptional cases severe symptoms may persist and treatment is required. The fibrocartilaginous disc of the temporomandibular joint was extirpated in 58 cases. Thirty cases were followed clinically for more than 4 years. Local anesthesia was used in the 20 patients operated upon by the author.

A vertical or angular incision over the joint and extending upward around the anterior border of the auricle has proved satisfactory.

The functional disturbances in the joint noted at the time of surgery were classified as follows: (1) luxation of the condyle of the mandible and disc in front of the articular tubercle on opening movements, (2) luxation of the condyle in front of the disc on opening movements (3) displacement of the disc on pediment to movement in the joint (4) an impingement on movement in the joint for which no cause was ascertained. (The upper joint exists between the disc and temporal articular surface and the lower joint between the disc and articular surface of the condyle.)

Macroscopic changes found in the disc consisted of nodular deformity of the surface, central lateral perforations and yellowish brown discoloration. Microscopically all but a few cases showed degenerative changes (hyaline and fibril degeneration, myxomatous degeneration, calcium deposits)

Extirpation of the entire disc necessitates disconnecting the upper portion of the lateral pterygoid muscle so that forward movement of the condyle is reduced. If further limitation of movement is required in luxation cases the lower part of the lateral pterygoid muscle may also be loosened. Plastic procedures for reducing motion in the joint are unnecessarily complicated procedures. The patients can masticate food usually in a few days after operation however there is usually pain on maximum opening movements for several months. Frequently there is slight crepitation in the joint after operation and sometimes also a slight limitation of motion. On opening of the mouth the jaw tends to deviate to the opposite side. The operation causes limitation of the ability to deviate the jaw to the operative side. Follow up examinations have shown no change in the joint not subjected to operation. Both local and peripheral symptoms of temporomandibular joint arthrosis have been immediately and permanently relieved by removal of the disc.

JOHN R. LINDEAY, M D

Mixed Tumors of the Salivary Gland Type J. E. Ash
Am J Orthodont 1947 33 332

The author believes the majority of the classic studies of mixed tumor of the salivary gland have been made with the preconcived idea that it was just another tumor of the salivary glands predominant of the parotid gland. He believes that much of the confusion concerning the histogenesis has arisen from the attempt to correlate the histogenesis with the embryology of the salivary glands. The modifying word "mixed" was originally used because it was thought that two embryonal layers must be concerned since both epithelial and mesenchymal elements were included. At present although the general opinion is that only one layer, either the dermo or endoderm is involved the term has persisted but now it implies a mixture of histologic rather than embryologic elements.

Any satisfactory argument must be based on definite functions. In selecting cases for this study the author's criteria are that the tumor contain an epithelial element which may range from basaloid to columnar mucin-secreting epithelium (not excluding the squamoid type) with diversified arrangement of solid masses of the basaloid or squamoid type through small, undifferentiated groups and through canaliculi to well organized acini and through mucinous, through gelatinous and myxomatous of chondroid and osteoid material, and even to mature cartilage and bone. Any combination of these epithelial and stromal elements identifies a mixed tumor. On this histologic basis the author has so far found 917 cases in the files of the Army Institute of Pathology and while they are predominantly from salivary glands, they have been found in other and bizarre anatomic situations.

An accompanying table shows that the parotid gland was involved in 503 instances.

Analysis of figures at large medical centers indicates that under ordinary circumstances the tumor is met with only occasionally. It may occur at any age, and several times it has been seen in infancy, although there has been no example of a congenital tumor. It seems to be the general experience that the majority of patients first come under observation when they are between 30 and 40 years of age. If the ordinary criteria of malignancy are strictly adhered to, salivary mixed tumor can be considered one of the benign tumors, although the possibility of recurrence is ever present.

No satisfactory histologic criteria on which to base prognosis have been recognized.

The tentative conclusion if any to be drawn from this analysis is that we must drop the term "salivary gland tumor" and use "mixed tumor" generically as referring to neoplasms that may arise in any organ or tissue containing glandular epithelium which is associated with a stroma sensitive to the "organs" of that epithelium. JOHN F. DIXON, M.D.

Central Myxoma of the Jaw. Kurt H. Thoma and Henry M. Goldman. *Am J Orthodont.*, 1947 33 534.

The purpose of this report is to call attention to a rather uncommon type of tumor found in the jaws, the so-called myxoma. Hitherto this tumor has been regarded as similar to that seen in the long bones which tends to recur and is often malignant. This study based on 21 cases, shows the tumor to be benign and perhaps of odontogenic origin.

Myxoma is a term used to indicate tumors which are composed of loose connective tissue with branched cells widely separated by a viscid, opalescent, mucoid fluid. While such tissue is not found in the adult body it does exist in the umbilical cord this tissue thus stands as the prototype of this tumor. However the myxoma is regarded by most pathologists as a modified form of fibroma in which a mucoid intercellular substance separates an embryonic type of connective tissue so as to resemble in appearance the tissue of the umbilical cord. Thus, a pure myxoma is rarely if ever encountered but a myxomatoid change in a portion or even the whole of some other type of connective tissue tumor is seen relatively frequently. JOHN F. DIXON, M.D.

PHARYNX

Carcinoma of the Tonsil. John H. Walker and Clifford D. Schulz. *Radiology* 1947 49 6.

The occurrence of carcinoma of the tonsils is relatively uncommon. In the present article the authors have reviewed the cases of all patients with carcinoma of the tonsil who had been treated with irradiation at the Collis P. Huntington Memorial Hospital Boston from 1936 to 1941 and at the Massachusetts General Hospital Boston, from 1936 through 1945.

Irradiation therapy was given in 90 cases. Eighty four per cent of the patients were males with a me-

TABLE II.—TUMORS OF THE TONSIL.
OVERALL SURVIVAL

7	61	3 (5%)
8	5	1 (20%)

^a Eleven patients did not have opportunity to survive and were not included in this analysis.

dian age of 63 years. This confirmed the common belief that cancer of the tonsils occurs most frequently in males in the seventh decade of life.

Because of the insidious onset, there was a median delay of 3 months before the patients sought medical attention. The most common complaints were sore throat and swelling of the neck. Lymph node metastases were often the first warning to the patient of the disease and this was present in over 60 per cent of the patients when they first consulted a doctor.

The majority of the tumors (87 per cent) were epidermoid carcinomas of varying grades. Tumor classified as grade I did not metastasize early although they were locally recalcitrant to irradiation.

Neck dissection was not employed in this series because of existing metastases, or the fact that patients were poor surgical risks. Both supervoltage and high voltage irradiation were employed. In general, as much radiation is directed into the tumor as can be safely tolerated by the overlying tissues. Detailed numerical formulas are given, and figures pertaining to periods of survival are shown in Table I.

Only 6 patients, or 15 per cent, have survived for 3 years or longer. The prognosis cannot be made on the grade of tumor alone. Patients with higher grade tumors (II and III) lived longer than those with grade I tumors. Lymphoepitheliomas gave the best response of all. As might be suspected, those patients who were free of metastases survived, on the average, considerably longer.

No striking advantage was evident from combined radium and roentgen therapy. When the recurrence did not appear until 1 year after the initial treatment, supplemental treatment appeared to be of definite value. At present it appears that supervoltage more effective than high voltage radiation.

The authors state that in general x-ray treatment alone gives results which are as good as those from any other single procedure or from a combination of several procedures.

ERNEST D. BLOCHMANTAL, M.D.

Massive Atelectasis following Tonsillectomy and Local Anesthesia: Report of a Case. Leroy Sawyer. *Arch. Otolaryng.*, 1947 46 45.

The author searched the literature for reports of massive atelectasis following tonsillectomy and

local anesthesia during the past 40 years and found 1 case recorded by Iglaue in 1857 who also mentioned 1 case each for Goodyear and Middleton. Clerk told the author of another case. In general surgery the incidence of another case has been vari- ously reported as causing from 3 to 70 per cent of all postoperative complications with a 40 per cent mor- tality. Among the predisposing causes favoring atec- tasis are oral sepsis acute or chronic upper respi- ratory infections, shock, and possibly allergy. Workers on the pathology of atelectasis revealed that excessive bronchial secretion plus the postopera- tive obstruction is the frequent pressure distal to the collapse. According to Brunn atelectasis is the ob- struction is the frequent pressure distal to the ob- struction. Cases have been reported in which the ob- struction occurred after a fall from a horse or a bicycle without the fracture of a bone or even a trivial bruise of persistent cough recurrent sore throat, and tonsillitis. On physical examination the throat found to have large hypertrophied tonsils and bi- lateral cervical adenopathy. Other findings were normal except for a slightly increased right hilar shadow on the roentgenogram. Preoperative medi- cation consisted of sodium amylal 3 grains, morphine 1/6 grain and atropine sulfate 1/50 grain. Procaine hydrochloride 1 per cent with epine- phrine 1 to 50,000 was used for local anesthesia. During the operation the bleeding was average in amount, which was readily controlled without liga- ture or stitches. At noon, the patient complained of throat pain for which she was given pantopon, 1/6 grain. There was no coughing or bleeding or further complaint during the day. At bedtime she was given sodium amylal 1 1/2 grains. Nearing midnight she complained of precordial pain and the next morn- ing she had severe pain in the right side of the chest, some coughing, a respiratory rate of 32, a pulse rate of 108, a temperature of 101.4 F, and a moderate leucocytosis in the blood count. Physical examina- tion showed diminution of breath sounds and de- creased tactile fremitus over the right lung with de- creased tactile fremitus and an impaired percussion note. The roentgenogram revealed collapse of the right lung, the heart margin well over to the right. Intercostal spaces narrowed and the right diaphragm markedly elevated. The next morning bronchoscopy was performed under local anesthesia and a bloody mucus plug was aspirated from the right main bron- chus. Immediately after the endoscopy the tempera- ture and the pulse and respiratory rates fell ap- idly and breathing became easier. Twenty four hours later another roentgenogram showed the tem- perature and the heart almost back to its normal posi- tion. The leucocyte count also became normal after a few days. The patient was seen 3 months and 1 year later respectively and the physical findings and roentgenograms gave normal results. The author

commented that the patient was given more than the average preoperative sedation. It seems that after a (Abstractor's comment) rather heavy preoperative medication, especially with the use of the time honored atropine sulfate which tends to dry the bronchial secretions producing viscid and tenacious mucus plugs, the postoperative administration of pantopon should not be encouraged as it diminishes cough reflex thereby favoring the oc- currence of atelectasis.) NECK

Determination of the Relative Activities of Anti- thyroid Compounds in Man Using Radioactive Iodine. Malcolm M. Stanley and E. R. Astwood. *Endocrinology* 1947, 41: 66.

It is difficult to evaluate the potency of antithy- roid compounds according to the response to treat- ment. Furthermore, general clinical experience in- dicates a discrepancy between clinical potency and designed a quantitative experiment on normal hu- man subjects to determine the potency of various compounds in preventing uptake of radioactive steps in iodine accumulation in the thyroid gland. (1) concentration of iodide ion in thyroid tissue which accounts for but a small fraction of iodine present in the normal gland, and which is inhibited by thiocyanate and (2) the synthesis of inorganic iodide into organically bound iodine. The latter step is thought to be inhibited by thiocyanate and similar compounds. Thirty two compounds and similar (12M) dose of 0.1 millicurie of radioiodine weakly alkaline solution. Iodine accumulation in the thyroid gland was measured by a special Geiger Muller tube placed over the isthmus of the thyroid. Four counts of from 20 to 40 seconds were made every 10 to 40 minutes during the first few hours of rapid accumulation then hourly for the rest of the day and finally at the end of 24 hours. The curve representing rate of accumulation was S shaped with the most rapid accumulation in the period from 14 to 4 hours. Except for the initial 14 hour period the curve had the general shape of a parabola and plotted against the square root of the elapsed time formed a straight line. In the test of an antithyroid agent the straight line function for iodine accumu- lation was plotted for 1 or 2 hours after administration of radioiodine then the agent was given and the degree and duration of change of direction of the line was expressed as a score of 0 to 5

- 0 = no effect
- 1 = slight or questionable inhibition
- 2 = definite but incomplete inhibition
- 3 = complete inhibition for 4 hours
- 4 = complete inhibition for more than 4 but less than 24 hours
- 5 = complete inhibition for 24 hours

Compound	Activity for human being	Activity for rat
Thiouracil		
Tetrahydro-6-thiopyrimidine		3

6-Ethylthiouracil		2
6-Cyclopropyl thiouracil		3
6- <i>n</i> -propyl-thiouracil	7.5	1.0
6- <i>n</i> -butylthiouracil	7.1	
Thiobarbital		7
Thiourea		
Thiocarbonyl-thioglycolic acid	3	
2-Mercaptoimidazole		
2-Thiolythiazole	2	4
2-Aminothiazole	1	5
2-Mercapto-2-amino 1,3,4-thiazole		1.5
Bisulfite	0.5	

Although there was considerable variation among subjects in the initial slope of the accumulation curve, the score of inhibition for a given compound was quite constant. There was also a close relation between dose and score. The table is abstracted from the complete table of Stanley and Astwood and lists only the more effective compounds comparing potency by the present test, and by the rat assay. Thiouracil has been given the arbitrary value of 1.

This method of testing based upon a single administration of the antithyroid drug does not indicate the relative potencies when repeatedly administered since cumulative effects might occur especially with longer acting substances such as thiobarbital and thiouracil.

CLAYTON H. THURKES, M.D.

The Use of Propylthiouracil in Hyperthyroidism

Arnold S. Jackson. *South. Surgeon*, 1947 15: 65.

The author reports his experience with 70 cases of toxic goiter treated by propylthiouracil, and refers data from 1,500 cases of other investigators. He states that to his knowledge there have been no deaths due to propylthiouracil among his own cases, only 1 presented a serious reaction to propylthiouracil, namely a leucocyte count of 2,500. The patient was a child of 9 years, who took 75 mg daily for 6 weeks. After a rest period of 2 weeks, iodine therapy propylthiouracil was resumed. However in a personal communication to the author, received February 7, 1947 Bartels stated that of 39 patients, 1 of them had a fever and 5 showed significant blood changes attributable to propylthiouracil.

Although the author's purpose in giving propylthiouracil is to prepare patients for surgery, he has not as yet operated on any children, although he had 4 children under 14 years of age as patients on propylthiouracil. Jackson concludes from his own experience and that of others that propylthiouracil has definitely replaced thiouracil as a much safer drug, but since propylthiouracil does not alter the pathology it is questionable whether it will prove curative in exophthalmic goiter, however he hopes it may prove curative in early mild cases. The greatest value of the drug is in preparation of bad risk cases of hyperthyroidism for thyroidectomy. These include the aged and patients with cardiovascular disease, diabetes, liver damage, or other complications.

The basal metabolic rate returned to normal more rapidly with propylthiouracil than with thiouracil, there was, nevertheless, much variation.

The author's procedure was to give 50 mg. of propylthiouracil on an average of 3 times daily the dose being varied according to the severity of the disease. As soon as the basal metabolic rate reached normal the patients were continued on small maintenance doses. A leucocyte count was made every 3 weeks.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

The Diagnostic Significance of Ocular Pain in Craniofacial Trauma T M Mokhov *Am Rev Seriet M* 1947 4 400.

The authors point out that the tentorial syndrome of pain in the eyeballs forehead and neck, accompanied by photophobia lacrimation and a marked increase in conjunctival and corneal reflexes has been known for several years. It is presumably due to irritation of the recurrent branch (nerve of Arnold) of the ophthalmic division of the trigeminal nerve. Likewise attention is called to the fact that in previous studies of localized pachymeningitis secondary to splinter injuries of the skull acute ocular pain is prominent on upward downward and lateral gaze.

With these reports in mind 100 wounded patients were examined for the diagnostic significance of ocular pain. At operation localization depth and character of the injury were noted. Acute spontaneous ocular pain followed by lacrimation and photophobia were found to be outstanding complaints in patients with meningeal involvement in the nuchal region. Ocular pain alone was more characteristic with lesions of the middle and anterior fossae. In cases in which injury had occurred in the convex frontal and central cerebrum ocular pain was present only upon movement of the eye balls. If the process became aggravated spontaneous pain made its appearance followed by photophobia and lacrimation in the acute phase. When ocular pain was present on movement of the eye balls it was frequently significant in localizing the lesion because pain occurs upon glancing to the affected side. Likewise spontaneous ocular pain was intensified in most cases upon glancing toward the side of the lesion. There was indication of a bilateral process or involvement of the tentorium if pain was equally acute in glancing in both directions.

Ocular pain either spontaneous or upon movement of eye balls, occurred in wounds with penetration of the dura by bony or metal splinters in depressed skull fractures or in local pyogenic lesions involving the dura. Pain was not observed when the dura scarred evenly when wounds due to metal or bone splinters were in the cerebral substance distant from the meninges or when fistulas had developed from the dura down to a deep cerebral abscess. Five case histories are presented in part to support the author's conclusions. RICHARD C. SCHWENKER, M.D.

Partial Excision of the Motor Cortex in Treatment of Jacksonian Convulsions: Results in 41 Cases. Cobb Plicher W F Meacham and T J Holbrook. *Surgery* 1947 34 653

Although excision of the motor cortex for treatment of focal epilepsy was first done by Horsley in

1886 this procedure has received relatively little attention until the last decade. The author discusses cortical resection in 41 patients who suffered from Jacksonian seizures. All had focal cortical convulsions without any gross cicatrization or space-occupying lesions of the brain. No patient was subjected to surgery unless failure or extreme difficulty of control with anticonvulsant medication had taken place.

The operation was done with the use of local anesthesia. After an osteoplastic flap had been reflected and the dura mater incised, electrical stimulation of the motor cortex with a unipolar electrode was done until the desired area was localized. In several instances the patient's convulsive episode was reproduced. After identification of the involved area, subpial cortical resection was done. In 6 patients (with focal sensory phenomena clinically) that portion of the postcentral gyrus corresponding to the extent of the precentral excision was also taken out.

The brain appeared grossly normal in 24 of the 41 patients. In the others there was arachnoidal thickening with grayish opacity or apparent shrinkage and atrophy of the convolutions. Microscopically the excised tissue was normal in 14 patients in 25 there was a distinct increase in glial elements and in 2 there was found to be an additional fibrosis.

Two phenomena were noted which strengthened the presumption of a hypersensitive cortical focus for this type of convulsive seizure.

1 Less voltage was required to produce a motor response in the area of motor cortex responsible for the focal attacks than was needed to cause a motor response elsewhere.

2 Stimulation of the appropriate cortical point reproduced the patient's seizure whereas stimulation elsewhere in the motor cortex caused only the conventional motor response.

Immediately following operation each patient showed a complete flaccid paralysis of the affected part. Spasticity developed gradually usually in 4 to 8 weeks. Within 8 to 20 days voluntary motor recovery had begun in all instances, and in 4 to 6 weeks perceptible voluntary movements had appeared in all muscle groups.

There were 2 operative deaths. Little or no disability occurred except in 4 patients with moderate (3 patients) or severe (1 patient) hemiparesis. Eight patients were completely relieved of convulsive episodes 12 showed pronounced improvement 8 improved to a lesser degree 8 had no improvement and 3 subsequently died.

The authors conclude that partial excision of the motor cortex in selected cases with focal motor convulsions is a valuable procedure.

C. FREDERICK KITTLE, M.D.

SPINAL CORD AND ITS COVERINGS

Lesion of the Intervertebral Disc Caused by Lumbar Puncture. A. H. Baker. *Brit. J. Surg.* 1947 34 385

A case history of an intervertebral disc arising from lumbar puncture is discussed. The patient was a 4 year old child who entered the hospital because of mild fits. Several diagnostic spinal punctures were done with difficulty at several levels along the lumbar vertebral column. About 1 week later the child had a severe backache, and a roentgenograph taken at this time showed no abnormality of the spine. After another week the pain was more severe and he had difficulty in sitting and walking. Roentgenograms were thereafter taken at intervals and showed a gradual narrowing of the spaces between the second and third and between the third and fourth lumbar vertebrae. The condition was successfully treated by plaster immobilization.

The author believes that such an injury is more likely to occur in a child than in an adult because the nucleus pulposus is more liquid and can seep through a ruptured annulus.

DANIEL ROCK, M.D.

Variations in the Syndrome of the Ruptured Intervertebral Disc in the Lumbar Region. Frederic V. Kristoff and Guy L. Odum. *Surgery* 1947 23 83

The authors have described the classical picture with regard to symptoms and neurological findings in the average single dislocated intervertebral disc. They point out the fact that there are variations in the clinical syndrome associated with other types of rupture of the intervertebral disc, with complications and progressive changes in the more simple types. The conditions outlined as responsible for such variations are classified as follows: (1) the rupture has taken place higher than the fourth lumbar interspace (2) lateral protrusion has not occurred or the protrusion is large enough to affect more than one or two nerve roots (3) the protrusion has been bilateral (4) 2 or more adjacent discs have ruptured (5) the main bulk of the ruptured disc is no longer attached to its intervertebral space but has wandered into the spinal canal (6) the protrusion is so massive that it completely blocks the spinal canal and thus produces the syndrome of the cauda equina.

Ruptures at higher levels as outlined above, in (1) may produce localized back pain without radiation over a radicular distribution.

Central protrusions are more apt to give localized back pain without radiation in view of the fact that they do not produce direct compression of a single nerve root. If this condition progresses to complete extrusion and obstruction of the canal one then finds a syndrome with the cauda equina as described under (6), with marked motor loss below the knees and as a rule loss of bladder and bowel control.

The bilaterally protruding disc (5) would, as expected, produce bilateral radiation of pain into both lower extremities.

Multiple ruptures of discs may be unilateral or bilateral, with unilateral or bilateral radiating pain and symptoms suggestive of involvement of the nerve roots at more than one level.

Displaced cartilage which may wander in the canal (5) may produce changing symptoms and findings, although the earlier symptomatology is usually that of a unilateral single protrusion.

Myelography will assist materially in reaching a final decision as to the presence of such unusual type of disc derangements.

HOWARD A. BROWN, M.D.

Erosive Bone Lesions and Soft Tissue Ossification Associated with Spinal Cord Injuries. (Paraplegia). Norman Hellbrun and William C. Kuhn. *Radiology* 1947 48 579.

A study of 99 cases of paraplegia was made to evaluate erosive changes and soft tissue ossification. The authors have emphasized that such ossifications are not specific for spinal cord lesions, but may develop in many diseases involving the central nervous system.

The x-ray examination included in all cases stereoscopic films in the anterior-posterior projection of the lumbar spine, pelvis, and hips. In 55 per cent of the cases further views were obtained of the knee, ankles, and heels.

Of the 99 patients, 45 showed erosive bone changes other than osteoporosis, while 43 exhibited soft tissue ossification. Only 4 cases revealed ossification of the tissues without bony changes. The extent of the erosive changes was, in the majority of cases, directly related to the severity, size, and duration of adjacent disability.

Roentgen studies had been made, on the average, at least one year after the cord injury. Early ossifying lesions of the soft tissue were not seen, but the authors believed that in all probability the deposition of a "flocculent, nebulous or streaky amorphous calcium" was the initial phase of the process. Ossifications are usually found near the larger joints but may occur in muscles, tendons, sheaths, ligaments, joint capsules, or be adherent to the periosteum. Although new bone may be contiguous to the periosteum it neither arises from nor affects it. Once a mature trabecular pattern is established the size of the ossification remains constant in the paraplegic patient, and regression does not occur. These soft tissue changes are never seen above the level of the spinal cord lesion.

The distinctive x-ray changes were first the erosive changes leading to the loss of normal contour of bone, as in the trochanter with flattening followed by reshaping and repair with the formation of an abnormal contour by proliferative and exuberant bone. Secondly there was complete lack of involvement of the joint surface or a decrease in the size of the joint space. All cases showed varying degrees of osteoporosis.

Biopsies of trochanteric bone from 10 patients enabled evaluation of the erosive process. All showed extensive subacute or chronic infection of the soft

issues with extension to the superficial portion of the bone. Within the bone itself there was increased asclerisation with gradual invasion of the marrow spaces by fibrous and vascular tissue. Finally there was progressive atrophy and resorption of bone and in a few cases, osteomyelitis with sequestration. There were no joint changes suggestive of neuroarthropathies and the question was raised whether this might not be due to the fact that paraplegic patients are not subject to the trauma of ambulation.

Etiological factors for the soft tissue ossification were discussed. Trauma was suggested as a probable underlying cause but the authors have pointed out that the neurogenic influence cannot be disregarded because of the great incidence of these lesions in neurological disorders. They suggested that trauma to the connective tissue might serve as a trigger mechanism in the development of the calcification when there has been disturbance of the nerve supply.

RICHARD C. SCHWEIDER, M.D.

SYMPATHETIC NERVES

Arterial Hypertension. Sven Hammarström. *Acta med. scand.* 1947 125 Supp. 192

The present monograph, dealing with the general subject of hypertension, is a combined study of the 134 patients in the series of the author, all of whom were studied on the medical service of St. Erik's Hospital, Stockholm. It is, as well, a digest of current thought and methods in the study and treatment of this disease. Many of the author's patients (101, or 75%) were treated by sympathectomy. In the first year all patients were operated upon by supradiaphragmatic sympathectomy only but all patients thereafter were treated by the more extensive supra-diaphragmatic and infra-diaphragmatic sympathectomy. The author is inclined to believe that the

more extensive operation is the more effective, but he makes the pertinent observation that the large series of results published by both Peet and Smithwick show essentially the same figures.

The height and variability of blood pressure in essential hypertension were studied by means of 24 hour readings, sodium amytal injections, nitrite administration, and cold pressor tests. The author separated his patients into three groups: patients with normal fundi, patients with arteriosclerotic eye-ground changes, and patients with frank hypertensive retinopathy. The author found no parallelism between the height of the blood pressure and the 24 hour variations. He does not consider the cold pressor test suitably standard for clinical purposes. There is a close correspondence between the spontaneous variability and the drop in blood pressure during the amytal test. In patients with hypertensive eye-ground changes the variation calculated according to nitrite tests is greater than the spontaneous variability while there is a close correspondence in those with normal eye grounds. In the author's experience vascular changes in hypertension are of greater prognostic importance than the height and variability of the blood pressure.

A general discussion of the methods of selection of patients for surgical treatment, the necessary pre-operative study and operative results the world over is given in a thoughtful, nonopinionated manner. The author has appended the summarized case histories of his operative patients and has assembled an excellent and up-to-date list of references from the current literature. The translator of this paper is to be congratulated since the English lacks many of the common grammatical errors in such reports. Altogether the monograph is recommended to any person interested in the broad subject of hypertensive disease.

JOHN MARTIN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Anatomic and Clinical Types of Mammary Tuberculosis. Tuberculous Galactophoritis. (Les formes anatomocliniques de la tuberculose mammaire. La galactophorite tuberculeuse) Jacques Delarue, Jean De Bruix, and J. P. Kerneis. *Ann. anat. path.* Par 947 7 146

Although mammary tuberculosis would appear to be a rather rare condition, only 473 cases having been collected up to 1936 the number of cases recently reported suggests that the disease may be more common than hitherto suspected. Diagnosis may require histologic examination. The authors present 18 cases of mammary tuberculosis, including an exclusively galactophoric type, to demonstrate the influence of mammary physiology and, in particular premenstrual congestion, on the local determinism and developmental stages of tuberculosis.

Clinically one may have to deal with exclusive involvement of the perimammary connecting spaces (paramastitis) or with lesions of the glands themselves, either of the deeper structures, or of the superficial perimammary region. Paramastitis is not mammary tuberculosis in the strict sense of the word, but consists of lesions of the thoracic wall in the mammary region.

Genuine mammary tuberculosis may be of the deep glandular type and may be diffuse or circumscribed the latter simulating fibroadenoma, sclerocystic mammitis or nodular cancer and frequently alluded to as pseudoneoplastic mammary tuberculosis—a superficial condition, of perimammary location. Most writers recognize lesions of the milky granulomata, abscesses, and sclerotic types. An attempt is made to draw a parallel between certain clinical aspects of the condition and the anatomicopathologic lesions in genuine mammary tuberculosis.

Milary tuberculosis of the breast is a rare localization of generalized milary tuberculosis. The authors observed the condition in 3 patients during lactation. It appears in isolated foci the size of a pinhead and is yellowish white in color. Histologically these lesions are intralobular: otherwise they are similar to the lesions of milary tuberculosis of other organs.

Genuine mammary tuberculosis may appear as a suppurative caseous focus, a veritable intramammary cold abscess, the size of which may vary from that of a nut to that of an orange, with a central cavity and one or several diverticula apparently corresponding to the galactophorous ducts. The rest of the gland is usually intact, occasionally it is the seat of a sclerocystic dysplasia. The cavity contains a yellowish gray or greenish grumous pus, with abundant fatty bodies and numerous Koch bacilli. The central cavity is bordered by an occasionally very thin margin which, on histologic examination, is shown to have a substrate consisting of a very thin

layer of caseous necrosis edged with epithelial cells in palisade arrangement.

Tuberculous mammary lobulitis is the substrate most deep circumscribed or diffuse types of mammary tuberculosis. The distinguishing features are integrity of the galactophore and of the periductal conjunctivoadipose tissue. The histologic features are described in detail. The lobulitis may be caseous and suppurative, or fibrous and hyperplastic, the latter being seen most frequently and comprising about 30 per cent of all cases of mammary tuberculosis.

Superficial perimammary mammary tuberculosis is a tuberculous galactophoritis other tissues remain intact. Histologically one may have to deal with circumscribed galactophoritis, with distended lactiferous ducts with pus proceeding from the caseified wall, or with vegetating galactophoritis with intracanalicular papillary vegetations, in which the bacilli are numerous. This is to deep tuberculous lobulitis and intracanalicular cancer is to deep mammary cancer. Associated lesions may include sclerocystic dysplasia or mammary cancer.

Mammary tuberculosis is an external hemipneumous form of tuberculosis which does not come with pulmonary tuberculosis. The minimal pulmonary lesions are the same as those observed in other forms of external tuberculosis, therefore the appearance of a mammary tumor in a patient with pulmonary tuberculosis should raise the suspicion of cancer rather than of mammary tuberculosis.

Opinions have been divided as to the mode of dissemination in mammary tuberculosis, the idea of a glandular invasion giving way to that of lymphatic and hematogenous spread. In deep or superficial glandular tuberculosis, however, the hematogenous route seems confirmed. The authors draw attention to the influence of certain nonspecific local favorable factors, and suggest that tissue biology may be more important in determining the lesions than the mode of dissemination and diffusion of the bacilli.

Finally the authors discuss the relation between mammary tuberculous lesions and the physiologic activity of the gland. Exacerbation of the disease during menstruation has been observed. With the exception of certain forms, mammary tuberculosis occurs only during the period of genital activity. The influence of lactation is manifest and milk is said to form an excellent culture medium for the bacilli. In 3 of the cases in the present series, tuberculosis of the breast developed 1 month after the beginning of lactation in 1 patient, and in 6 months after the beginning of lactation in 2 patients.

The effect of the menstrual cycle is still more important. During the last days of the cycle the patient complains of a painful tension in the breast and more severe pain than usual in the involved breast. The swelling is increased. In a case of galactophoritis, a cyclic course was noted. On the eighteenth day

of the cycle a sensation of painful tension was noted with redness at the site of the fistula on the twentieth day a clear serous fluid escaped from the fistula. On the twenty first day this was replaced by pus which persisted to the twenty-eighth day when the discharge ceased suddenly. The fistula closed on the fourth or fifth day of the period. These phenomena were repeated for 8 months and failed to respond to ultraviolet rays or vitamin A therapy. Bacilli were not found in the serous discharge but appeared in the pus escaping from the twenty-second to the twenty-eighth day. On the last day the discharge became sterile. Only the injection of male hormone in doses of 50 mgm. per month for 3 months during the second quarter of the menstrual cycle prevented these symptoms, and the patient has remained well for 1 year. Thus, folliculin seems to favor tuberculous activity possibly via the local angioneurotic vascular system. It is evident therefore that the course of mammary tuberculosis is influenced by hormonal factors. This is another proof that local nonspecific factors play a part in determining the course of mammary tuberculosis.

ENTRÉ SCHEMATIC MOON

TRACHEA, LUNGS, AND PLEURA

Reflex Infection, Pulmonary Re-Expansion and
Resorption Pulmonary Retraction (Infection pleura,
Sera) Marcelle Roux Berger Blanchy J. Méd
Chir., 1947 : 97

The end result of a pleural infection may be a residual abnormal pleural space or an adhesion of the re-expanded lung to the thoracic wall. The former may remain aseptic. Thus superinfected pleuritis during the course of pneumothorax may be cured by pleural lavage following which the therapeutic collapse can be maintained. Primary pyogenic consolidation on the other hand are likely to heal with re-expansion of the lung which becomes adherent to the thoracic wall. This symphysis prevents recurrence. Should the suppuration fail to respond the infection and pulmonary retraction persist. Attempts at treatment of the pulmonary retraction by physical methods rarely lead to complete re-expansion. The only logical treatment in cases in which the suppuration has become chronic consists in the excision of the infected tissue and destruction of the septic areas. Physical therapy cannot take the place of prompt disinfection and pleural aspiration under these conditions may prove dangerous.

The author stresses the fact that in most cases of pleural infection in which the lung fails to re-expand there is another factor besides the pathologic and toxic condition to consider namely a temporary independent obstacle of a functional nature. This is after its removal. It is due to the effect of the pleural inflammation on the subjacent organ and muscles surrounding it. An illustrative case is described in detail. In this case the intricate local and functional

signs included a parietal reaction leaving one half of the chest flat and immobile with marked lowering of the shoulder marked diminution of the intercostal spaces and rapid superficial upper costal respiration even on the normal side. There was a bilateral contraction of the diaphragm with immobilization in the position of inspiration. A superficial spasmodic cough followed the slightest movement of deglutition speech or deep respiration. The pulmonary retraction was very rapid and attempts at pleural depression were followed by epigastric pain spasmodic cough and immediate pleural hemorrhage. As soon as the pus into a serofibrinous fluid indicated control of the infection the pulmonary retraction disappeared, with simultaneous disappearance of the parietal and diaphragmatic reactions. This pulmonary reaction to an inflamed serosa resembled acute peritonitis. The only effective treatment consisted in suppression of toxic resorption by abundant, frequent and antiseptic pleural irrigation.

This early apparently reflex, pulmonary reaction evidently depends more upon the suddenness and severity of the pleural involvement. The virulence of organisms, intensity of inflammation than upon the amount of effusion. It does not occur in pyogenic pleuritis. Some pleuritis occurring during pneumothorax treatment for tuberculosis run a very acute course with fever, cough, dyspnea, vomiting and complete gastric intolerance for several days. They are then accompanied by the described early pulmonary retraction. The effect of lavage is not influenced by the duration of the retraction since the latter preserves its functional character as long as the pleural infection remains curable. In cases of long standing it may be difficult to determine whether the functional nature of this active reflex, temporary retraction is still preponderant or whether it has been replaced by a sclerosis. Even sclerosis may retrogress in cases are described illustrating the remarkable capacity of the lung to re-expand once the cause of suppuration has been removed. Treatment of osteitis in one case and excision of a costal focus of infection in the other led to recovery when other methods had failed.

The function of reflex retraction in response to physical chemical or electric stimulants and of expansion under the influence of pharmacodynamics has therefore to be considered as well as the physiologic and respiratory functions of the lung. It is emphasized that pleural dysfunction should therefore take precedence over mechanical measures for pulmonary re-expansion. In the serofibrinous pleuritis thorax pleuritis early copious irrigation should be used in preference to puncture and aspiration. In superinfected pneumothorax pleuritis such irrigations must be used very early and daily in order to leave no trace of pathologic fluid in the pleura. The irrigations should be done with 2 needles as far as possible from each other the lower one at the lowest

anterior or posterior point of the focus as determined by a lipiodol guide. The upper needle insures a free circulation of air above the fluid. Attempts at pleural depression will lead to pleural hemorrhage which favors microbial proliferation. Irritating substances such as antiseptics must be used with caution. Penicillin is so well tolerated that it supplants all other drugs for this purpose. It is, however, not always adequate in severe infections without total evacuation. In primary pyogenic pleuritis, drainage should be made from the lowest point after lipiodol orientation, since any retention however minimal will hinder recovery. Daily irrigations should be made to free the pleura from pathologic secretions before penicillin is introduced. Continuous aspiration insures permanent drainage, but the probe must be in the cul-de-sac and watched so that it does not cause hemorrhage or the slightest malaise. It must not be used alone or in preference to the other methods described. The procedures insuring best and earliest pleural disinfection are those leading to most rapid pulmonary re-expansion with symphysis and definite cure, whatever be the pleural pressure left in free communication with the exterior.

ESTHER SCRAMER MOORE.

Thoracoscopy and Pneumothorax in Pulmonary Tuberculosis. Walter E. Kunzler. *J Thorac. Surg.* 1947 6 353.

Every patient with pneumothorax should be closely guarded against possible complications, and should be submitted to thoracoscopy as soon as direct or indirect signs of adhesions are detected. Indirect signs are (1) the presence of fluid in the costophrenic angle (2) insufficient collapse of diseased lung tissue, cavities, and persistence of positive sputum, in spite of regular and apparently sufficient refills and (3) partial shift of the mediastinum. Direct signs of adhesions may be recognized only at a later date, but expiratory x rays, oblique aereo x rays, tomograms, and outlining of the esophagus by radiopaque substances make it possible to establish such a diagnosis before indirect signs are available.

Thoracoscopy is a harmless procedure. Its only potential complications are subcutaneous emphysema and hemorrhage from the trocar puncture. General anesthesia is of definite disadvantage. Local infiltration with novocaine is the anesthetic of choice.

Adhesions should be divided if (1) they are responsible for an insufficient collapse of the diseased part of the lung or (2) if they are suitable for separation without anticipation of complications, such as injury to lung tissue, rupture of residual adhesions, perforation of cavities, and hemorrhage. Adhesions of major caliber or multiple small adhesions should not be divided if selective collapse is possible, especially in bilateral cases.

Multistage operations should be attempted only if no other procedure is feasible, if intrapleural pressures are well controlled and if prevailing circum-

stances permit a further stage at any time considered optimal for the individual case.

The determination of vital capacity or of oxygen consumption of each lung separately (pneumometry) should be done in the presence of bilateral disease. Bronchoscopy should be performed in all cases before institution of pneumothorax, if this is possible.

Pneumothorax should be abandoned immediately if (1) important adhesions are not suitable for entry and other procedures (thoracoplasty, lobectomy, pneumonectomy) (2) fluid and high fever develop and persist for more than a few days, (3) conditions which predispose to the development of emphysema are present, especially injury to the lung by its cavity rupture of residual adhesions, or of a cavity and extensive active disease of the lung (4) oxygen consumption is below the minimum compatible with light exercise (5) tension cavities are present. In bilateral far advanced cases, with severe repeated hemorrhage originating from the pneumothorax, however it may be advisable to continue the pneumothorax.

In 75 per cent of the series of 500 cases reported, pneumonolysis converted a pneumothorax which was questionable or dangerous, due to adhesions, into a safe and satisfactory collapse of the lung. Favorable results from pneumonolysis are dependent on the skill of the operating surgeon. Experience is important, since teaching of the technique is rather difficult, due to the endoscopic nature of the procedure.

SAURITZ KUNZ, M.D.

Lung Resection for Pulmonary Tuberculosis. Charles Philmore Bailey. *J Thorac. Surg.* 1947 16 323.

This article presents a general and far moving discussion of the use of resection for tuberculous pulmonary lesions. The feeling is expressed that it is a justifiable procedure deserving of accurate appraisal. The author states that it is "under some cloud because of the dramatically poor results first obtained." Further experience may clarify the indications and many of the details in management.

The most common causes of mortality and morbidity are given as (1) asphyxia during operation by flooding of the airway with released secretions, (2) spread of the disease to other areas, (3) hemorrhage or shock, (4) opening of the bronchial suture line, (5) tuberculous empyema, (6) pyogenic empyema, (7) combinations of items (4) (5) and (6) and (8) marked deviations from normal of intrathoracic pressure levels postoperatively.

The prevention of these complications is discussed. Items (1) and (2) being closely related, can be minimized by proper positioning on the operating table so that the secretions are not allowed to gravitate in such a way as to invade uninvolved segments of lung.

A special technique of endobronchial catheterization has been worked out in order to prevent the secretions from entering these segments. This tech-

Fig. 1

 Fig. 2. Obturator removed. It is really a 5 mm. bronchoscope with a built-in light carrier and oxygen delivery tube. Battery cord is connected to terminal.
 Fig. 3. Flexibility of tube after removing obturator. This decreases trauma to the air passages.

unique is adequate in numerous situations but has the undesirable feature for example of occluding the orifice of the upper lobe when the right side is intubated. The author uses it in total pneumonectomy and lower lobectomy chiefly.

Hemorrhage and shock are combated by the usual means.

The closure of the bronchial stump is accomplished by a row of end sutures of fine silk or stainless steel wire, reinforced by a second proximal row which reduces the tension on the end row. The line of resection is then treated with plasma and thrombin and covered by pleura or other suitable available tissue.

Prevention of empyema involves adequate cleansing and dressing of the pleural cavity in the event of contamination and prompt re-expansion of the lung following lobectomy. This can be greatly enhanced by negative pressure drainage; reduction of the size of the hemithorax by phrenic nerve interruption and/or thoracoplasty. These various procedures

are discussed as to their relative indications and usefulness.

The mechanism of changes in intrapleural pressures postoperatively, the dynamics of cough in the face of surgically produced alterations of function, and the attendant effect on the control of bronchial secretions is elaborated upon.

The author's experience comprises 80 cases treated by resection for a variety of pathologic states in tuberculosis. The mortality is given as 36.5 per cent for pneumonectomy and 35 per cent for lobectomy; there was none for segmental resections. The over-all mortality is estimated at 27.5 per cent. Since operative complications may not cause death for months or years, it is difficult to estimate the actual operative mortality, but the author believes that a reasonable estimate of mortality from resection for cases in which no other form of treatment is possible should be around 20 per cent. At present 68 per cent of the living patients have negative sputum and are well.

HIRSH T. LANGSTON, M.D.

Cysts of the Pulmonary Pedicle (Les kystes du pédicule pulmonaire) P. Santy M. Bérand, and P. Galy *J. méd. chir., Par* 947 66.

In addition to dermoid cysts of complex structure involving multiple tissues one may also encounter in the mediastinum, or its immediate vicinity congenital cysts of more simple structure involving tissues only of a single organ. The latter develop later in embryologic life. They may be epidermoid cysts, pleuropariocardiac cysts cysts derived from the digestive tract or bronchiogenic cysts of the pulmonary pedicle. The authors describe 4 cases of the latter type in which surgical removal of the cysts led to recovery. A review of the literature shows that about 30 such cysts have been discovered at operation in adults. Also teratological malformations in fetuses and young infants have been reported. This type becomes manifest very early because of symptoms of compression. A brief résumé of cases reported by other writers is presented. The patients in the present series were 16 11 34, and 38 years of age respectively. The smaller cysts are usually juxtamedialastmal but as they grow larger may assume variable positions and may be encountered at the level of the tracheal bifurcation, upper hemithorax, at the base of the thorax, especially on the left side, or in the interlobe. The position varies according to the site of implantation of the cyst and its stage of development. Cysts of the lobar pedicle usually have a more insidious course. Some cysts appear to have only a distant relation to the pedicle as in 1 of the present cases in which the cyst was located in the triangular ligament.

Macroscopically the walls of these cysts appear smooth thick, and whitish or slightly pink, and are often covered with vessels of considerable size. On section they prove resistant and are found inseminated with tiny islets of cartilaginous tissue. In none of the cases described was there any wide direct communication between the cyst and the large bronchi of the pulmonary pedicle but in 1 case a small communication existed between the cyst and the bronchial tree. Broad communications were described in only 1 cases in the literature. As a rule, there is no communication and especially not in infants and young children. The cyst may be free of any adhesion outside of the pedicular zone or may have important connections with large vessels. Occasionally there may be dense adhesions to adjacent pulmonary lobes or the pericardium usually associated with infection. In most cases the contents of the cyst are a thready glairy mucus, usually described as sticky. In rare cases it may be a yellow fluid. In 1 of the cases reported, it contained flakes of cholesteroline. If the cyst becomes infected puncture will yield pus.

Histologically the inner surface of the cyst wall is lined with ciliated cylindrocubical epithelial cells of bronchial type. In infected cysts this lining may be partially or almost completely desquamated. In some cases the lining appears to have undergone a transformation, which suggests a possible transition

to epidermoid cyst or secondary local metaplasia. The wall of the cyst contains also different degrees of normal bronchial tissue. The organization of these elements and their greater or less relative importance permits classification into 3 distinct types which are described in detail.

These types include (a) an aspect much like that of normal bronchial tissue, (b) a more complex aspect, seen in larger cysts, produced by an such disposition of the various planes and excessive development of certain structures. In particular the cartilaginous and (c) certain other aspects which are much less complex and differentiated.

Cysts of the pulmonary pedicle are caused by maldevelopment of the bronchopulmonary system in the division of the bronchial tree. They are believed to have their origin in an accessory rudimentary bronchial bud. In some cases there may be malformation of a normal lobe or an accessory pulmonary lobe, while in other cases there may be a supernumerary lobe accompanied by cystic bronchial malformation.

Clinically these cysts may remain silent or they may be associated with vague malaise pain in the chest or epigastrium stubborn cough, dyspnea and bloody sputum. The symptoms are more severe in association with the larger cysts and are often exacerbated in certain positions or changes of position. Roentgenologically the shape of the cyst changes with change of position. Painful reflex changes as well as vascular reflexes causing hemoptysis, as well as release by traction on the peribronchial nerve plexus. If infection develops, the picture becomes that of chronic pulmonary suppuration. Progressive enlargement of the cyst seems common, and in late cases has proceeded for periods ranging from 10 to 25 years. Compression, infection, and hemorrhage supervene. For this reason a pedicular cyst should be surgically removed as soon as diagnosed regardless of the symptoms.

Diagnosis depends chiefly on the x-ray findings. The technique and interpretation of roentgenography for this purpose are discussed.

Artificial pneumothorax is another diagnostic technique although not always possible because infected cysts often lead to emphysema. A clear demarcation between the retracted pulmonary lobes and the cyst may be demonstrated in fairly large cysts. In smaller cysts no such demarcation is observed and it may be impossible to determine whether the tumor is intraparenchymatous or extraparenchymatous. Changes in the shape of the tumor may, however, aid in the diagnosis of a cystic structure. Once pneumothorax has been attained pleuroscopy will reveal the location of the cyst, its shape dimensions, and relation to the diaphragm and adjoining pulmonary lobes.

Bronchoscopy or lipiodol bronchography may be of value in eliminating the bronchi as the origin of hemoptysis, or in disclosing a bronchial anomaly or the opening of a supernumerary bronchus, or some anomaly in lobar distribution. Caution is urged in

the use of bronchography once operation has been decided upon because retention of lipiodol in the alveoli may give rise to postoperative complications. Differential diagnosis from atypical pleurisy and intrapulmonary tumor encysted pneumothorax, supradiaphragmatic encysted pleurisy, cancer hydatid cyst, and nonparasitic pulmonary cysts is discussed. Diagnosis may be impossible without thoracotomy in some cases. A fluid level is rarely found in a pedicular cyst. In differentiation from intrathoracic but extrapulmonary tumors pleuroscopy will eliminate diverticulum of the pericardium, neurofibroma, dermoid and epidermoid cysts the latter usually defying diagnosis before operation. If thoracotomy fails to reveal the true nature of the cyst histologic study may be required.

Treatment is purely surgical and should not be delayed once the cyst has been diagnosed. When vascularization or aeration of the adjacent pulmonary lobes renders complete removal too dangerous it is justifiable to open the wall of the cyst, remove most of it, and leave the adherent portion *in situ*. Subtotal excision is preferable to lobectomy or pneumonectomy.

The results obtained with excision are excellent. All 4 patients in the present series recovered even though lobectomy was required in 1 case. The lesion does not involve the pulmonary parenchyma and excision entails no functional mutilation.

EMILY SCHAEFER MOORE

HEART AND PERICARDIUM

Surgical Treatment of Pericarditis Constrictiva

Kaare Lannung *Acta chir scand* 1947 95 440.

The author reports on the surgical treatment of 9 cases of pericarditis constrictiva. Cardiolytic was performed on 2 patients and one of these died a few hours after the operation. In the patient who survived there was no effect from the operation. In 7 cases, partial pericardiectomy was performed. There was no postoperative death. In 4 cases a considerable improvement followed the operation. All 4 of these patients are fit for work and are practically symptom free.

In 3 cases the period of observation has been long viz., 5 to 8 years. In the fourth case it has been only some months. In 1 of the 3 remaining cases the result may be good but the period of observation is too short. In 1 case it is doubtful that any effect will follow the operation. In 1 case the operation had no effect and this patient died 3 years after the operation.

It is recommended that the operation be performed under intratracheal narcosis and that a dorso-lateral transpleural incision be used as this gives a good approach to the heart, and a thoracic wall can be reconstructed after the operation. It is further more recommended that operation be performed at a sufficiently early stage in the disease before irreversible changes in the liver and myocardium have occurred.

JOHN J. MALONEY M.D.

Results of Pericardiectomy in the Syndrome of Pick.

(Resultados alejados de la pericardiotomía en el síndrome de Pick) Arnaldo Yódice. *Bol Acad argent cir* 1947 31 395

In a study of 7 cases of compressive pericarditis (Pick's disease) the author has found tuberculosis as the etiological agent, although there are some cases of infectious pericarditis due to common organisms.

With the fibrinous reaction the pericardium undergoes a constrictive process which little by little compresses the heart and interferes with diastole. This results in increased venous pressure and brings about hepatomegaly which in turn gives rise to increased pressure of the portal system and results in ascites and edema of the lower extremities. The ensuing hepatic cirrhosis is believed to be due to the hepatic congestion.

Patients with constrictive pericarditis and ascites show the following symptoms: general debility, fatigue, dyspnea on slight exertion, swelling of the abdomen, venous engorgement, cyanosis, dyspnea on recumbent position and dilatation of the jugular veins and the veins of the hands and forearm. The pulse is generally rhythmic and regular and has a rate of 60-100 while in the cases with tachycardia, it signifies myocardial damage and a sign of tuberculous pericarditis. Pulsus paradoxus is present in nearly all cases. The arterial pressure is low (100-120 mm) and is associated with a low pulse pressure (30-35 mm). The venous pressure varies directly with the cardiac compression, ranging between 15 and 42 cm of physiological saline solution. There is a direct relation between the degree of ascites and the venous pressure.

The fibrous pericardium prevents the transmission of the apex beat in systole. The heart tones are muffled and lessened while the electrocardiogram shows low voltage and a serrated Q.R.S. On roentgenography the principal signs are the narrowing of the width of the heart and the absence of diastolic dilatation. Calcification of the pericardium is observed in 25 per cent of the cases while in the author's series it was found in 4 of 7 cases. Hydrothorax signifies a tuberculous pericarditis.

This disease must be differentiated from tuberculous peritonitis, hepatic cirrhosis, asystole and hypostyle.

Ample pericardiectomy is indicated except in poor surgical risks, or patients with a high temperature. Preoperatively the patient should have a salt free diet and digitalis if tachycardia is present. The anesthetic used was nitrous oxide with a little ether. After the heart is approached the fibrous pericardium is dissected from the apex to the base and to the great vessels. During this maneuver the heart reacts with extra systoles which if too frequent indicate a period of rest. Drainage to a dependent point is used and the wound is closed in layers.

Complications during surgery are as follows: acute dilatation of the heart and ventricular fibrillation which may be treated with electric shock therapy. To prevent immediate postoperative complication

the patient should be placed in an oxygen tent for 3 days, and cardiac tonics and penicillin should be administered.

The cure is of the Pick's disease, but not of the underlying tuberculosis. In the author's series all of the patients recovered except 1 who had millary tuberculosis.

ARTHUR F. CIPOLLA, M.D.

ESOPHAGUS AND MEDIASTINUM

Diverticulum of the Esophagus. A. C. Furstenberg.
Ann. Otol. Rhinol. 947 50 305

Pharyngoesophageal diverticulum is a herniation of mucous membrane through a weakened region at the junction of the inferior constrictor and the cricopharyngeus muscles. An obstruction of the esophagus contributes to its development. The diverticulum can now be safely removed in a one stage operation because of the effectiveness of sulfadiazine and penicillin in preventing mediastinal infection. The technique of the operation is described in detail.

CLAYTON H. THORNE, M.D.

Megaeosophagus (II megaeosophago) A. Bonardies.
Arch. Ital. Med. Exp. Appl. 947 3 79.

The various theories treating with the etiology and pathogenesis of the esophageal dilatations, although usually backed by ingenious and thought provoking probative material, are largely repudiated by the author as either not explaining all the facts observed or as explaining all the facts in only a few selected instances. It is hard to see how the hereditary or congenital factors suggested in some of these theories could be present, at times to an advanced age without giving any evidence, or at least more than passing evidence of their presence. They could hardly represent more than a predisposing factor in the development of the disease. Even the assertion that the condition arises as a result of a continuing spasm of the sphincter surrounding the lower end of the esophagus seems implausible in the face of the fact that no special thickening of these muscles at this location has ever been demonstrated. The "cravatte" of muscular fibers described by Joanesco represents only a delicate muscular band on the anterior surface of the esophagus whose evident purpose is to anchor the esophageal tube and not to function as an accessory mechanism in the act of deglutition.

The idea that a tumor (cancer) acts as the blocking agent at the lower end of the esophagus is rendered implausible by the fact, among others, that the tumor when actually present does not tend to produce more than a slight dilatation of this tube moreover when the lower end of the esophagus in megaeosophagus is dilated by operative means the size of the esophagus tends to return to normal, whereas when the tumor is removed in those cases the dilatation remains. Those instances in which the tumor is actually found in a case of true megaeosophagus are more easily explained as a sequela of the irritation and trauma of the food material in over-

coming the dysphagia rather than as the cause of the dilated condition.

The author nevertheless, does not dismiss the possibilities in any of these suggestions, but before a number of different factors acting in concert must be considered. First, it must be assumed there is present a congenitally weak esophageal musculature which (combined perhaps with a malfunctioning of the vagosympathetic nervous system) might go along for years with disagreeing symptoms until a sudden fright or period of anxiety serves as the proximate cause of an acute attack. In this regard a case is cited of a 15 year old girl, who had always been well and of a gay and carefree temper, but who during an air raid at Palermo, developed inability to swallow and a radiologically dilated esophagus. This condition was later completely relieved by an insignificant dilatation operation during a period of residence in the relatively tranquil city of Rome. In this same case as interest in the possibility of reducing the patient's participation in the production of the syndrome by the fact that an ameporrhea developed, simultaneously and disappeared at the same time as the dysphagia.

Another instance suggesting the power of emotional stress in the production of megaeosophagus was communicated personally to the author by Professor Puri. It was that of an aviator whose plane was shot down in aerial combat. For a year this patient was considered a malingerer until radiology decided to dilated esophagus. This patient likewise was only relieved after the cessation of hostilities.

Finally there are cited the instances of a young man whose condition was relieved, apparently by the power of suggestion, following a dilatation attempt which unknown to the patient, had failed as the result of a technical mishap, and of a boy who screamed and struggled in the operating room and could not be persuaded to submit to the operation, but who was perfectly and permanently relieved.

Diagnostic probing of the esophagus is dangerous and as a rule, unnecessary. If the radiologic examination is insufficient to confirm the diagnosis the author resorts at once to the esophagoscope. Likewise, preliminary meddling such as antispasmodic medication is passed over in favor of immediate treatment with the dilating procedures. In many cases a large sound will be all that is necessary however the author has obtained most excellent results with the modern mechanical dilators. One patient was satisfactorily relieved by the Goldstein dilator (as modified by Einhorn), but most of the author's experience has been with the dilator of Starck. With this apparatus, one dilatation has usually been sufficient although an occasional recurrence after a year or so has been rectified by a second dilatation. No harm has ever been observed from the use of these machines. Radical surgery has been reserved for a few patients with impervious stricture or massive cicatricial narrowing who could not be relieved by nonoperative methods. JOHN W. BARNARD, M.D.

MISCELLANEOUS

Subdiaphragmatic Aberrant Pulmonary Tissue.
(Case Report.) Anibal Roberto Valle and M.
Lawrence White, Jr. *Dis Chest* 1947 13 63.

The authors report the case of a 9 month old colored male infant who had projectile vomiting of mucus and undigested food after nearly every feeding since birth. There was no choking, cyanosis or coughing associated with the vomiting. Bowel habits were normal. The child was mentally alert but was unable to gain weight normally. Atropine taken orally failed to relieve the symptoms and the patient was admitted to the University of Virginia Hospital for treatment of a suspected diaphragmatic hernia.

The child was poorly nourished and weighed only 10 pounds, 10 ounces. His temperature was normal. The abdomen was distended and tympanitic. The remainder of the examination was not contributory. All laboratory studies were found to be essentially negative.

Gastrointestinal roentgenograms showed a short dilated esophagus with a large gas-filled stomach, the cardiac portion of which protruded through a 2 cm. diaphragmatic defect near the esophageal hiatus. The remainder of the examination was found to be negative.

It is believed this patient had a diaphragmatic hernia, but the large tympanitic stomach suggested also increased vagal tone. Atropine was given for 15 days without much change in the clinical or roentgen picture.

Exploration was carried out through the eighth rib bed and an obvious posterior diaphragmatic herniation was found. The hernia was egg sized, herniated mass seemed to contain a nonreducible solid viscus. After opening the thin attenuated diaphragm, a dark red friable mass of tissue was seen. It was believed to be an ectopic kidney or spleen. Subdiaphragmatic exploration revealed a normal stomach, liver, spleen and kidney. The mass of tissue was dissected free from the diaphragm and posterior parietal peritoneum, with difficulty. There were numerous large vessels, apparently from the aorta, entering the mass. The mass was mobilized and removed. The defect in the diaphragm was closed with interrupted

silk. The child died suddenly as the chest was being closed, presumably from operative shock.

Postmortem examination revealed a small right kidney (10 gm.). No other congenital abnormality or explanation for the persistently dilated stomach was found.

The 4 by 3 by 2 cm. resected specimen was reddish brown with a cystic center 1 cm. in diameter containing bloody fluid. Microscopically the tissue appeared to be lung tissue with all alveoli filled with red blood cells. There was no pneumonia or neoplasia.

Two types of aberrant lung tissue are reported—the tracheal lobe in the upper chest, connected by a bronchus with the trachea, and the lower accessory lung in the lower chest or upper abdomen, consisting of sequestered pulmonary tissue having no connection with the bronchial tree. Thirty seven cases of the latter type, including the author's, have been reported. These cases are listed with information as to the side, whether above or below the diaphragm, and whether associated with a diaphragmatic hernia.

This anomaly is not incompatible with life, 1 case each being reported in patients 6, 18 and 47 years of age. Only 4 in the series were found on the right, and in 11 cases diaphragmatic hernias were associated. The author's case is the sixth one of hernia occurring beneath the diaphragm, the second in this location associated with a diaphragmatic hernia, and the first one diagnosed during life by an exploratory laparotomy.

There are many theories about the formation of aberrant lung tissue. Cockayne and Gladstone suggested that during certain embryonic stages, adhesions occur between the lung mesenchyma and the celomic mesothelium. These adhesions cause the living mesenchyma to be displaced downward along with the foregut. This would possibly account for the formation of a diaphragmatic hernia and the attachment of the accessory lung to the lower esophagus and stomach seen in the author's case.

The second theory is based on the possibility of the development of a second primitive respiratory tract from the digestive tract. This could be accomplished by a downward displacement of cells from the tracheoesophageal ridge with the growing foregut.

ROBERT R. HIGGINS, M.D.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

New Technique for Studying the Cytology of Gastric Aspirates in Man. Franklin Hollander, Manfred Hess, and Herbert A. Sober. *J Nat Cancer Inst.* 1947 7 365

The authors previously studied and reported the impairment of the mucus barrier in dogs including the attendant desquamation. If the response of the human stomach to mild irritation is analogous to that of the dog, then the introduction of an irritant into the gastric cavity of man should similarly induce greater quantities of desquamated epithelium than can be aspirated from the unstimulated fasting stomach. The present report is a discussion based on the collection of gastric aspirates following suitable stimulation of the mucosa, and the cytologic study of smears prepared from them.

A 3 per cent eugenol water suspension was used as the stimulus in fasting human subjects. The exact technique of aspiration at intervals is described. Smears from each sample were prepared and air dried without other fixation. They were stained with toluidine blue. The technique differed considerably from that reported by Papanicolaou but the methods will be used in systematic studies on human beings. There was a considerable yield of mucoid material. Mild irritation resulted in a striking increase in desquamation of individual columnar cells, clumps, and ranks of these elements. Squamous epithelial cells, leucocytes, and bacteria are also frequently noted in smears. In addition to being an aid in the study of the physiology of gastric mucus secretion in man, the finding that cancerous cells can be desquamated by eugenol may prove of value in the diagnosis of adenocarcinoma in the early stages of its development.

HARRY W. FOX, M.D.

A Review of 112 Cases of Congenital Hypertrophic Pyloric Stenosis. R. McLaren Todd. *Arch. Dis Childh.* Lond., 1947 22 75.

Congenital hypertrophic pyloric stenosis is one of the common diseases encountered during the first few weeks of life. When a survey of the literature is made, the wide variation of the mortality rate reported with both medical and surgical treatment is striking. An attempt was made to discover the factors which determined the success or failure of the treatment adopted from records of various observers. It appeared that one of the main causes of failure was inadequate attention to the details of treatment.

From a study of 112 cases, certain conclusions as to treatment were drawn and some interesting results of the roentgenological follow-up were noted.

One hundred and twelve cases of congenital hypertrophic pyloric stenosis treated medically are presented. Series A comprises 40 consecutive cases with 2 deaths, and series B comprises 72 cases treated at

the same hospital over an 8 year period with 6 deaths.

Particular stress is laid on the observation of definite routine, whichever method of treatment is employed.

The cases in series A were followed up clinically and roentgenologically. The subsequent physical and mental development of the patients was in no way affected by the pyloric stenosis, but the delay in emptying time of the stomach when seen at the follow-up examination was proportional to the severity of the condition as judged by the length of hospital treatment.

The cases in series B were followed up clinically and some of the patients were submitted to roentgenological examination. The results tend to confirm those of series A.

The following rules regarding the method of treatment should be employed in cases of congenital pyloric stenosis:

1. Medical treatment should be routine unless the patient is grossly dehydrated.
2. Surgical treatment should be undertaken if medical treatment is ineffective after a 7 day trial, unless the patient has an infection.
3. Surgical treatment is indicated in patients who are grossly dehydrated when first seen, or whose birth weight was below 6½ pounds.
4. Surgical treatment is contraindicated in an infected patient because of the risk of fatal gastroenteritis.

CHARLES BAXON M.D.

The Nutritional State of Patients with Peptic Ulcer as Measured by Vitamin Levels in the Blood and Urine. David Cayer and Sophia Cady. *Gastroenterology* 1947 9 54.

Disturbances of nutrition in patients suffering from gastrointestinal disorders, particularly with vomiting, deranged motility and self-imposed or therapeutic dietary restrictions are well recognized. As a result, an increased interest in dietary therapeutics has been of marked benefit to the patient. An unfortunate result, however, has been the overly enthusiastic and needless administration of expensive vitamin preparations to many patients in whom there is no indication for such treatment and who, therefore, can expect no improvement from the therapy. Indeed, who may at times show vague or definite gastric symptoms because of the medication.

On the basis that current laboratory methods for the determination of vitamin levels in the blood and urine were a fairly accurate measure of nutrition, and that the findings of such tests correlated with clinical evidence of vitamin deficiency, the authors have utilized these procedures to study the nutritional status of a group of 20 male patients suffering from active, recurrent peptic ulcer as compared to a control group of 15 patients without gastrointestinal disease.

The authors found that as a group patients with peptic ulcer were not likely to have deficiencies of vitamin A, niacin, or riboflavin a tendency which is in keeping with the infrequency of clinical signs of vitamin lack in such patients. Vitamin A and riboflavin are supplied adequately in the large amounts of milk which most ulcer patients consume and the normal amounts of niacin excreted in the urine of these patients possibly is due to a liberation from the body stores of this substance during even prolonged periods of inadequate dietary intake. There is little evidence that a lack of vitamins A, C, niacin, or riboflavin is an etiologic factor of the disease, and the authors conclude that the need for routine administration of these substances in peptic ulcer cases is doubtful. In any event the recommended daily doses of riboflavin (5 to 25 mgm) and niacin (100 to 150 mgm) are considerably more than can be utilized.

Pernicious Anemia and Susceptibility to Gastric Neoplasms. Henry S. Kaplan and Leo G. Rigler *J Lab Clin Med* 1947 31 444.

Statistically both cancer and adenomatous polyps of the stomach are reported associated with pernicious anemia more frequently than in normal patients. The average duration of pernicious anemia prior to the onset of cancer when it occurs is approximately 8.7 years. The apparent increase in gastric cancer morbidity in addition anemia is generally explained by the greatly increased life expectancy since the introduction of liver therapy. The incidence of cancer in patients with pernicious anemia is from 5 to 20 times that which would be expected on the basis of chance alone.

Gastric polyps are found at autopsy in the stomachs of patients with pernicious anemia 10 to 16 times more frequently than in other conditions. The nature of the etiologic relationship is not clear. Adequate anti-pernicious anemia therapy does not prevent the development of gastric carcinoma. Features common to pernicious anemia and gastric gastritis include achlorhydria and atrophic gastritis and hereditary gastritis does not seem to be a causative factor in pernicious anemia for these stomachs show no inflammatory changes. Likewise, pernicious anemia is not more common in the stomachs of cancerous individuals than in those of other individuals of comparable age. There is a high incidence of achlorhydria in relatives of patients with pernicious anemia and about 18 per cent of patients with pernicious anemia also have relatives with that disease. The fact that the gastric mucosa is a known storage site for the blood group-specific agglutinins suggests a further possible association with heredity. While observations to date are not statistically conclusive the present evidence suggests that the two diseases have common hereditary influences. The practical importance of these observations resolves into the early detection of gastric cancer which is the chief problem in stomach cancer today. The routine roentgenologic or gastroscopic exami-

nation of all patients in the gastric cancer bearing age (i.e. 40 years and over) would entail an enormous expenditure of time effort and money with a very small yield of tumors. Only 2 carcinomas were found in over 2,400 asymptomatic individuals past 50 years of age using a rapid fluoroscopic technique and none were found in 500 apparently healthy men over 45 years of age. Statistically about 3 individuals per 1,000 over 40 years of age are likely to have carcinoma of the stomach hence the necessity for selecting patients for routine periodic examinations of the stomach on the basis of some pre-existing disease or symptom with which the occurrence of gastric cancer can be shown to be associated. To date the only known indicator of this type is pernicious anemia. The authors present the results of serial roentgenologic and gastroscopic examinations in a series of patients based on this criterion.

Total number of patients with pernicious anemia examined	Carcinoma of stomach found	Adenoma polyps of stomach found	Total tumors of stomach found
259	18 (6.9%)	17 (6.6%)	35 (13.5%)

Patients with pernicious anemia must represent a very small fraction of those susceptible to gastric cancer. Series of patients with other indicators (achlorhydria, chronic gastritis, gall bladder disease and anemia) and relatives of patients with gastric cancer are being studied in an effort to find the criteria for mass surveys for the early detection of neoplasms of the stomach.

Pernicious Anemia and Tumors of the Stomach. Leo G. Rigler and Henry S. Kaplan *J Nat Cancer Inst* 1947 327.

Within the past 15 years increasing attention has been drawn to the coexistence of pernicious anemia and epithelial tumors of the stomach. That this association is more than accidental has been demonstrated by a number of large-scale statistical studies of postmortem cases and of living patients. The precise nature of this relationship is still far from clear. Three hypothetical possibilities are enumerated: (1) pernicious anemia is still far from cured; (2) gastric cancer directly produces gastric cancer; and (3) the two diseases are linked through a precursor or manifestations common to both. It has been suggested by Teufel that liver extract used so successfully in the treatment of pernicious anemia might contain a weak carcinogenic agent which, on successful administration, could lead to cancer in a susceptible individual. Recent experimental support of this startling suggestion warrants further study. According to these authors the best indicator of gastric cancer is pernicious anemia, while achlorhydria is considered the next best criterion. Routine roentgenograms may yield only a very small percentage of tumors if carried out on an unselected population over the age of 50. However, there is reason to expect that routine examination of symptomless individuals by means of roentgen rays

will result in the detection of gastric tumors in an early stage of development. Even rather large malignant neoplasms have been found in symptomless patients. Unfortunately patients with pernicious anemia represent a very small fraction of those susceptible to gastric cancer.

It seems desirable to effectuate a simple, rapid method for the routine roentgen examination of the stomach in symptomless individuals. Fluoroscopy alone results in a number of errors. The combination of fluoroscopy "spot" films, and a series of roentgenograms of the filled stomach is expensive and impractical on a very large scale. The possibility of utilizing some method of photofluorography or cine-roentgenography such as that advocated by De Castro should be seriously considered.

HAROLD LAUFMAN, M.D.

An Attempt to Identify Likely Precursors of Gastric Cancer. David State, Richard L. Varco, and Owen H. Wangensteen. *J. Nat. Cancer Inst.* 1947 7 379.

In 1945 a co-operative clinical study group was set up in the University Hospitals (Minnesota) embracing the Departments of Pathology, Radiology and Surgery in an attempt to define some of the likely precursors of gastric cancer. It was thought that persons with (1) achlorhydria, (2) gastric polyp, (3) pernicious anemia and (4) relatives of patients with proved gastric cancer would be more liable to develop carcinoma of the stomach than those who do not fall into these categories.

At the beginning of this study all male patients 55 years of age or older and female patients 65 years or older registering for the first time at the out patient clinic, were subjected to a gastric analysis employing 3 successive doses of 0.5 mgm. of histamine as a stimulant to gastric secretion. Those patients showing achlorhydria then had their stomachs examined gastroscopically and roentgenographically. If no gastric lesion was found, each achlorhydric patient was given a reappointment slip for a repeat examination in 6 months. After January 1, 1946 the age level for inclusion in the study was lowered for both female and male patients to 50 years or older. Also it became obvious that it would be profitable to study patients with histamine hypochlorhydria as well. Two hundred and thirty-eight patients were found to be achlorhydric to 3 successive doses of histamine, 67 were achlorhydric to 1 consecutive dose, and 45 were achlorhydric to 2 doses. An additional 30 patients were found to be hypochlorhydric (less than 20 degrees of free acid) after 3 successive doses of histamine. In these groups 4 unsuspected carcinomas of the stomach confirmed at operation, and 10 patients with gastric polyps were discovered. A third carcinoma of the stomach failed to be identified through a misinterpretation of the roentgenograms of the stomach.

Seventy nine patients with pernicious anemia were examined roentgenographically but no gastric carcinomas were found in this group.

Gastric carcinoma appears to occur more frequently in the relatives of patients with gastric carcinoma than in patients with noncancerous gall-bladder disease, hemorrhoids, hernia or rectal carcinoma, although these differences were not sufficiently great to be statistically significant. The unsatisfactory response of relatives to requests for an examination indicates that an active program of cancer education for the public is urgently needed. An additional 9 patients with gastric polyp obtained from the hospital records were placed under observation. Local excision of the polyp or gastric resection was done in 12 instances without discovering gastric cancer. Of 40 patients with occult blood in the stool, 20 suspected gastric cancer was found.

Studies such as this might well be undertaken on a large scale in many of the great medical centers of this country but would require large amounts of money and a spirit of co-operation on the part of the patients.

HAROLD LAUFMAN, M.D.

The Cytology of the Gastric Fluid in the Diagnosis of Carcinoma of the Stomach. George K. Papanicolaou and William A. Cooper. *J. Nat. Cancer Inst.* 1947 7 357.

For several years the authors have worked out a technique of diagnosing cancer through the recovery and identification of exfoliated neoplastic cells. This was first applied to the vaginal and uterine secretions for the diagnosis of cancer of the female genital tract. Later the work was extended to the examination of other fluids, such as urine, sputum, pleural and peritoneal exudates, and more recently the gastric secretion.

The specimens were obtained by emptying the fasting stomach with an ordinary Levine tube of whatever secretions it had accumulated. An equal volume of 95 per cent alcohol was immediately added to the aspirated specimen and this was sent to the laboratory. A detailed description is given regarding the handling and staining of these specimens.

The cytology of the gastric fluid is unique in that many of the cells are derived from other organs. Squamous cells of the esophageal or oral mucosa are sometimes found in the gastric fluid, as are cells foliated from the respiratory epithelium, the latter frequently being carried into the stomach by the swallowing of bronchial discharge. Normal cells of the gastric mucosa are of the columnar mucoid type and appear singly or in clusters. They are usually inconspicuous or totally absent and only rarely appear in large numbers.

The identification of cancer cells is facilitated by their abnormal traits, the most characteristic of which involve the nuclei. These are nuclear enlargement out of proportion to the size of the cells, mitotic activation, unequal fragmentation, hyperchromatism and large and atypical nucleoli. In adenocarcinoma the cells are more rounded and resemble adenocarcinoma cells from other organs. In mucoid carcinomas one finds many columnar forms in which the presence of mucin can be demonstrated.

SURGERY OF THE ABDOMEN

Although single cancer cells are often pathognomonic, a positive diagnosis should be based as much as possible on clusters which offer additional criteria such as crowding, irregularity of pattern, anisocytosis and anisonucleosis, engulfment and lack of definition of cell boundaries. In the clinical correlation of 137 cases there were 10 false negative 7 suspicious and 10 positive diagnoses in 27 cases of cancer. Three of the 10 cases that were missed proved to be scirrhus cancer. In this type of cancer desquamated cells are usually scanty or totally absent. As the authors have gained experience with the method they have learned to be cautious about recording specimens in which the cellular elements are degenerated and advise that such specimens be discarded entirely. Two cases of the 10 reported correct as definitely positive were of particular interest. One was a lesion of the cardia in which there were a gastric ulcer after x ray examination, at the operation and following gross pathological study. Only on microscopic study was a small cancer seen in one quadrant of the ulcer.

The authors emphasize the preliminary nature of this work and warn that there are many technical problems that remain to be studied. It is hoped that the accuracy of this method will improve with more experience.

The Radical Surgical Treatment of Gastric Cancer

George T. Pack. *J. Am. Cancer Inst.* 1947 7 337

It is pointed out that there is a great margin for error in reporting end-results for the treatment of gastric cancer, especially regarding the question of operability. The pronouncement by any surgeon of the inoperable state depends on (1) the condition of the patient; his age the coexistence of degenerative diseases and the complications attendant on the presence of the cancer (2) the extent of the disease i.e. the degree of involvement of the stomach and extension to and incorporation of neighboring viscera by the cancer and metastases to the regional and distal sites (3) the surgical philosophy moral point of view courage and experience of the surgeon.

With a knowledge of the inevitability of death from cancer of the stomach that is not treated, no surgeon would refuse a patient the slightest chance for cure or even relief because of the fear of criticism or an unnatural pride in low figures for operative mortality. Nor should any surgeon attempt to "play God" and decide arbitrarily that a certain patient with gastric cancer has lived a sufficiently long life or that he has so few remaining years of even normal life expectancy that operation at best would hardly be worth while. In the Gastric Service at Memorial Hospital in New York approximately 50 total gastrectomies have been performed for cancer of the stomach but of the adjacent lymph nodes bearing regions as well which include all the lymph nodes along the lesser and greater curvatures of the stomach the greater omentum in its entirety the para-

pyloric and retropyloric lymph nodes. In instances the peritoneum of the lesser omentum is stripped off with the specimen. The jejunal lumen is anastomosed to the esophagus either in front of the transverse colon. The anastomosis is fortified by suturing a flap of diaphragmatic peritoneum anteriorly and posteriorly below the anastomosis in order to suspend the jejunum and give additional strength to the anastomosis. A lateral anastomosis or enteroenterostomy is done in order to provide a short-circuiting of the bile and pancreatic juice between the proximal and distal jejunal limbs and in order to provide a suitable egress for any swallowed food which enters the proximal jejunal limb.

The operative mortality for total gastrectomy is 30 to 30 per cent as compared with 8 to 12 per cent for subtotal gastrectomy. The chief complications of the operation have been of pulmonary origin rather than infections in the peritoneal cavity. The author has found that the complication of severe anemia is not encountered so frequently as one might anticipate in view of the important role the stomach or duodenum plays in hematopoiesis.

The 8 to 10 per cent of patients with cancer involving the gastric cardia are no longer classified as incurable because the surgeon is now able to pursue an upward exposure of the cancer bearing segment to include the cardiac end of the stomach and the abdominal and thoracic esophagus so as to carry the resection high thereby insuring complete removal of the tumor and adjacent lymph nodes. A small exploratory upper left midrectus incision is made in order to ascertain the presence or absence of hepatic and peritoneal metastases. The extension of the cancer to regional lymph nodes the mobility of the cancer and the amount of distal uninvolved stomach findings warrant subsequent anastomosis. If exploratory incision is then extended upward through the costochondral cartilages and laterally in the seventh intercostal space to intercommunicate the thoracic and abdominal cavities.

The resection of cancers of the gastric cardia in the author's experience has increased to 58 per cent of the total number of patients subjected to laparotomy or thoracotomy.

Improvement in end results in the treatment of gastric cancer is attributable to a greater awareness on the part of the general public the improved facilities for the diagnosis of cancer the wider application of surgical resection by an increased number of surgeons who are performing the operations in numerous hospitals throughout the United States and finally by the introduction of extremely radical surgical procedures of 3 types (1) removal of the organs adjacent to the stomach that are involved by contiguous with the cancer (2) total gastrectomy when the cancer involves the major part of the stomach and (3) transthoracic transdiaphragmatic cardiectomy for cancers involving the gastric cardia. The total number of patients salvaged from those having the disease is inevitably increasing. A better appreciation

of proper preoperative and postoperative care and wider appreciation of the metabolic disorders coincident with and related to gastric cancer have also served to increase the salvage rate in the surgical treatment of this disease. HAROLD LAUFMAN MD

Gastric Operations. Robert M Zollinger and Stanley O Hoerr. *J Am Med Ass* 1947 134 575.

Few if any surgeons accept the fact that from 5 to 25 per cent of patients who have undergone gastric operations have symptoms related to the ingestion of food. The majority are inclined to call an operation successful only if there is no recurrence of the benign or malignant ulcer. Some of the symptoms reported either as mild or as severe and disabling attacks are sensations of warmth, sweating, dizziness, faintness, palpitation, nausea, and abdominal pain. It is believed that these symptoms are related to a carbohydrate-rich diet.

It has been suggested by Lapp and Dibold that the attacks are due to hypoglycemia occurring several hours after meals. It is believed that the condition represents an increased rate of sugar absorption due to more rapid delivery of sugar into the jejunum. Sugar taken well before the period of hypoglycemia, is advised.

Glaesner (1940) reported a condition of hyperglycemic shock characterized by nausea, vomiting, sunbar pains, visual disturbances, convulsions, and cardiac disturbances. He believed that the rapid absorption of sucrose, and not the delayed hypoglycemia, was responsible for the symptoms. The suggested treatment was small doses of insulin before meals in patients who exhibited these symptoms.

Custer and associates have described the "dumping syndrome" characterized by nausea and weakness, a feeling of warmth, cold diaphoresis of the face, and cardiac palpitation. The incidence of these symptoms in two groups subjected to gastric resection for benign ulcer was 5 and 12 per cent. They believe these symptoms are caused by sudden mechanical distention of the unprepared jejunum. The suggested preventive was an operation with a smaller gastrojejunal stoma. Ephedrine for slow gastric emptying, dilute hydrochloric acid and small feedings low in carbohydrate are suggested in the treatment of this syndrome.

Evenson studied gastric motility and dextrose tolerance curves in a group of controls (medically treated ulcer patients) and patients who had had a gastroenterostomy or resection. He found gastric motility is increased and emptying time decreased in patients with gastroenterostomy or resection. These patients also show an abnormal dextrose tolerance curve with a rapid and high primary rise and a rapid fall to low values. These curves are believed due to more rapid absorption, a consequence of more rapid gastric emptying.

The authors studied a series of 25 patients after gastric operations, and the majority of these patients had digestive complaints. The operative procedures were carried out for duodenal ulcer, gastric ulcer, and

gastric carcinoma. There were 21 men and 4 women whose ages ranged from 26 to 65. The time had elapsed varied and in some cases was over 10 years.

Ten of the patients showed both a hyperglycemic and hypoglycemic in one or more dextrose tolerance tests. 7 patients showed only hyperglycemia, and 4 showed hypoglycemia. Only 4 of the 25 showed neither hyper nor hypoglycemia.

Of the 25 patients with ulcer, 14 had some type of complaint during the course of the dextrose tolerance test. The complaint did not always coincide with the extremes of the blood sugar level. Ten of the 25 patients gave a history of postoperative discomfort of the type considered in this study. It was possible to correlate them with the blood sugar levels. In one group of patients the symptoms appeared shortly after eating and in the other group, after a brief period of an hour or longer.

Study of the protocols shows that abnormal absorption of sugar and outward symptoms do not depend on a direct connection between the stomach and jejunum. The condition may persist for many years. There is an unusually steep curve in a patient who has had a total gastrectomy. Individual susceptibility must play some part in the production of symptoms since steep curves with hyperglycemia did not always lead to symptoms. Other patients showed symptoms even though the blood sugar never rose to high levels. Blood sugar levels after meals high in fat and protein were only half those after meals high in carbohydrates. This indicates the value of eating small quantities of foods which are low in carbohydrate content.

The authors believe there are two distinct syndromes following gastric surgery—one appearing shortly after eating and one occurring after a latent period of an hour or more. They state that both syndromes may occur in the same individual. The later symptoms are due to hypoglycemia in most instances.

There is considerable disagreement as to the cause of these symptoms. Hyperglycemia and mechanical distention of the jejunum are not satisfactory explanations. There is considerable evidence favoring an abnormal carbohydrate absorption as being an important factor.

There are a number of contributing factors, such as (1) increased gastric motility (2) an abnormal rapid delivery of food into the jejunum, (3) failure of normal dilution of hypertonic solutions of sugar in the stomach, (4) an abnormally rapid absorption of sugar from the duodenum (5) possible effects of distention of the jejunum, and (6) the susceptibility of the individual.

Attack on any one of these factors may help in controlling symptoms. Therefore any attempt to slow gastric emptying will help. Perhaps it will be easier to provide smaller feedings with lower carbohydrate content to slow down the rate of sugar absorption and the possible irritative action on the jejunum.

It is believed that many patients who have submitted to gastric surgery can be benefited by regulation of their carbohydrate intake

ROBERT R. BROWNE M D

Surgery in Radiation Injury of the Stomach Ralph F Bowers and Irving B Brick. *Surgery* 1947 22 30

The authors present 6 cases of radiation effect on the stomach requiring surgical intervention. Similar cases have not been previously reported elsewhere. Perforation of radiation induced ulcers in the antral portion of the stomach was noted in 3 cases and hemorrhage was also noted in 3 cases. In 1 of which there was also a perforation. In the other case an uncomplicated ulcer at the pylorus was found. Radical surgery was required in chronically ill patients in whom the procedure is made additionally difficult because of the presence of radiation injury to the small intestine in some cases. The result of the gastric surgery has been satisfactory but complications incident to radiation injury in other parts of the gastrointestinal tract have appeared in some cases. It is emphasized that patients receiving similar amounts of radiation without apparent gastrointestinal injury have been observed, which accentuates the marked individual variability of response of the tissues of the gastrointestinal tract to radiation

JOHN J MALONEY M D

Total Gastrectomy Reginald H Smithwick. *J England J M*, 1947 237 39

A survey of the literature indicates a noteworthy recent decrease in operative mortality following total gastrectomy. Because of this it seems proper to utilize this operation somewhat more frequently particularly in cases in which a lesser procedure may jeopardize the chance for cure, because of an inadequate margin of safety beyond the gross limits of disease. Although the lower current operative mortality rate for total gastrectomy is undoubtedly due to a combination of factors, it is believed that improved surgical technique is one of the most important.

A closed (aseptic) method for esophagojejunostomy is described. This technique of anastomosis may further reduce the operative mortality by minimizing the hazard of peritonitis due to local contamination. The procedure is as satisfactory as open methods of suture, and has been found useful in all portions of the gastrointestinal tract.

The author presents a report of 2 cases in which the patients are living and well 5 years and 2 months, and 10½ years respectively following total gastrectomy for carcinoma. The latter appears to be the longest recorded survival after total gastrectomy for carcinoma.

STUART KATZ M D

Total Gastrectomy Henry K. Ransom. *Arch Surg* 1947 55:13

By total gastrectomy is meant the removal of the entire stomach with a cuff of the esophagus above and of the duodenum below. With the many advances

in preoperative and postoperative care and the better anesthetic methods there has resulted a reduction of the operative mortality. While this mortality is still disturbingly high it is not prohibitive. In addition it can now be stated that a person can live a reasonably comfortable life without a stomach.

The author reports a series of 60 cases of total gastrectomy over a 9 year period. The oldest patient was 81 and the youngest 30. There were 14 deaths, or an operative mortality of 23.3 per cent. General peritonitis was the most common cause of death and was usually due to leakage at the site of the esophagojejunal anastomosis. Of the 46 patients who survived the operation, 31 have subsequently died. In all instances death was due to recurrence of the malignant disease. The average duration of life in this group was 50 months. Eleven patients are still living after operation for carcinoma. Approximately one half of these were operated on too recently for evaluation of the result. Three patients may be classified as representing 5 year cures.

All of the patients with benign lesions who survived operation are living and maintain a satisfactory state of nutrition. In 2 patients the classic picture of pernicious anemia developed approximately 5 years after operation.

The technical details of the operation are discussed and the value of the procedure is considered.

HARRY W FINE M D

Two Hundred and Fifty Four Pathologic Specimens Obtained by Gastric Resection. Study of the Lesional Types, Topography and Histopathology (254 Piezas de resección gástrica. Estudio de la frecuencia de los tipos lesionales. topografía de las lesiones e histopatología) H Lorenzo, Lozada, and Br Séliska Piovano. *Arch surg med* 1947 30 64.

The authors studied 254 surgical specimens obtained by gastrectomy. Of these 173 were ulcers, 111 gastric and 62 duodenal. According to the authors the differentiation between ulcerated cancer and a benign ulcer which has become neoplastic is based on the fact that benign ulcers which undergo carcinomatous degeneration show a destruction of the muscular coat of the stomach whereas ulcerated carcinomas do not.

Using this criterion the authors found that 59 of 254 were primary carcinomas and that 79.66 per cent of these occurred in males. Of 111 gastric ulcers, 17 (15.3%) became cancerous. 13 of these occurred in men and 6 in women.

The article is illustrated by several interesting histological sections and pictures of gross specimens.

WILLIAM E. RICKETTS, M D

Anatomic Variations of the Vagus Nerves—Their Significance in Vagus Neurectomy J Allen Chamberlin and Theodore Winship. *Surgery* 1947 22 1

The authors' article is based on studies of 30 esophagi removed at autopsy. The specimens in

cluding the lower trachea, main stem bronchi, and a portion or all of the stomach in as many cases as possible. A few specimens obtained early in the course of the work were studied and dissected in the fresh state, but it was later considered advisable to complete the studies on fixed specimens inasmuch as more accurate evaluation of all fibers could thereby be made. The ages of the patients from whom specimens were removed ranged from 5 to 80 years and the ratio of males to females was approximately equal. Body sizes were, of course, variably represented and there was no apparent relationship between body sizes and the sizes and character of the nerves. The course of the vagi from the level of the primary bronchi to the stomach was studied, the general structure of the so-called esophageal plexuses was noted, and the general relationship of the nerves to the stomach was examined in a number of specimens, but special emphasis was placed on the study of variations in appearance, formation, and distribution of the gastric divisions of the vagi which form the anterior and posterior esophageal plexuses and course to the stomach through the esophageal hiatus.

For purposes of simplification a classification was decided upon which would enable the authors to place the specimens studied into classes based on certain major anatomic variations of the gastric divisions of the vagus nerves at the supradiaphragmatic levels. The classification is as follows:

1. Simple or basic pattern, in which a single, primary trunk forms from the anterior and posterior esophageal plexuses, forming thereby the so-called left, or anterior and the right or posterior nerves and entering the hiatus as single trunks. The classification of the specimens is based on the general character of the nerve or nerve complex between the levels of the esophageal plexus and the upper level of the diaphragm.

2. Intermediate pattern, in which a single primary trunk forms from the anterior or the posterior esophageal plexuses or both but divides into two or more secondary nerve trunks before entering the hiatus in their course to the stomach.

3. Complex pattern, in which two or more primary trunks form from the anterior and/or the posterior esophageal plexus or plexuses before entering the esophageal hiatus in their course to the stomach regardless of the number or character of the secondary nerve trunks.

From the analysis of the material, it can be concluded that a distinct majority of the gastric divisions of the vagi are of a simple pattern, with a single trunk representing the left, or anterior nerve and a single trunk representing the right, or posterior nerve. In this series, 30 specimens, or 60 per cent, were placed in this classification. Relatively few specimens fell into the intermediate classification. Eight specimens, or 16 per cent, were of this pattern, in which single trunks were formed from the anterior or the posterior esophageal plexuses, or both but presented two or more secondary trunks which formed from the primary trunk before entering the

esophageal hiatus. Twelve or 24 per cent, of the specimens were of the complex pattern, in which there was more than one primary trunk formed from the anterior or the posterior esophageal plexuses or both. These figures suggest that a distinct majority of the cases encountered should present single posterior nerves which lack an immediately supradiaphragmatic complex and consequently present no technical difficulty in accomplishing a complete bilateral vagus neurectomy. The few intermediate types which one encounters should involve somewhat greater technical difficulty in that the operator should attempt to locate the primary trunk of the complex, and division should be made at this point. If this is not done and division is attempted above or below this level one becomes involved in the fibers which make up a part of the complex esophageal plexus or in the multiple secondary trunks which enter the hiatus. One is thus confronted with the potential danger of incomplete division of all the fibers courting to the stomach. Inasmuch as the pattern does not occur in great numbers and must be chosen with care in choosing the proper level for division complete neurectomy should be accomplished, as need have little fear of operative failure. However, recognition of the fact that this pattern does occasionally occur is important. The fact that 12, or 24 per cent, of the specimens were of the complex pattern should be taken seriously; a knowledge of these anatomic variations is essential and the clinical importance of the occurrence of these multiple primary trunk patterns should be recognized.

As has been previously indicated, the most common location of the gastric nerves or nerve complexes has been found to be within an area just above the diaphragm between the anterior midline and a point just anterior and medial to the true left lateral position for the left nerve, and between the posterior midline and a point just posterior and medial to the true right lateral position for the right nerve. These positions have been designated as normal and fibers of the gastric divisions of the vagi which have been found located outside of these areas have been designated as abnormal in position. Of the anterior nerves or nerve complexes examined, 44, or 88 per cent, were found in the so-called normal position and only 6 or 12 per cent of the specimens were in abnormal positions. Of the posterior nerves or nerve complexes 41 or 82 per cent, were in normal position and 9, or 18 per cent, were in abnormal positions. Of the posterior nerves, 3 specimens presented complexes which were in normal position, but each with a single fiber which was in an abnormal position. It is gratifying to note that the anterior and posterior gastric nerves usually are found within fairly limited areas. However, since there are occasional variations in their locations and since there are rather marked differences in the sizes of the nerves, some of which are quite obscure one must recognize the fact that some fibers may be overlooked at the time of vagotomy and an incomplete division results.

As far as the gross morphology of the nerve fibers is concerned 92 or 73 per cent were oval in shape and 34 or 37 per cent were flat, or ribbonlike. None of the nerves appeared as round fibers. Many of these would be difficult to palpate and a few of indicated later in the discussion of the number and percentage of obscure fibers noted in the series.

Of the fibers examined 88 or 70 per cent were considered distinctly prominent and should have been easily palpated and visualized at operation. 21 or 16 per cent were moderately prominent but should have been easily demonstrable. 17 or 14 per cent were considered obscure and would have had to be sought for meticulously at the time of vagotomy.

The more complicated patterns occur in sufficiently great numbers to justify serious consideration of the best methods of performing the vagus neurectomy in order to be more certain of complete division of all fibers. When the operator is certain that complete division is possible if the primary gastric nerve trunks are divided, one would feel that this is the procedure of choice. However, if there is doubt, particularly when the pattern is very complex, it would seem that the procedure of choice would be in effect a "stripping" of the vagus fibers from the level of the hilum to the gastric fundus. Further in view of the varied patterns and distribution of the gastric divisions of the vagus nerves, one would be led seriously to question the use of the abdominal approach as a routine procedure for vagotomy. For the surgeon who is only occasionally performing vagotomy this would seem particularly to apply.

JOHN J. MALONEY, M.D.

Intestinal Obstruction: Analysis of 352 Cases.
W. Hendricks and W. D. Griffin. *Surg. Clin. N. America*, 1947, 27, 51.

Intestinal obstruction is a most hazardous diagnostic problem because there are no absolute criteria to differentiate between simple and strangulating obstructions. The authors present an analysis of 352 cases of bowel obstruction (exclusive of 138 cases of incarcerated and strangulated external hernias). There were 168 cases of obstruction of the small bowel and 184 cases of obstruction of the large bowel.

Of the small bowel obstructions adhesions were considered the etiologic agent in 58 per cent of the cases. Pain, vomiting, and distention were the outstanding symptoms being present in 80 per cent of the cases. A scout x-ray film of the abdomen (supine position) was diagnostic of obstruction in 65 per cent of the cases and a great aid in determination of the type and the location of the obstruction. Visible gas in distended loops of small bowel is considered absolutely diagnostic of stasis of the intestinal contents.

Early diagnosis and early surgical decompression in obstruction of the small bowel have been emphasized. Enterostomy was necessary in only 3 cases.

In 98 per cent of the cases the cause of the obstruction was corrected directly. Resection was necessary in 34 per cent of the cases. In most of these the anastomosis was performed by an open end-to-end anastomosis with interrupted sutures throughout. An overall mortality of 27.9 per cent is reported in the cases of small bowel obstruction.

In 60 per cent of the patients with large bowel obstruction the condition was due to carcinoma. The left side of the colon was involved in 81 per cent and the right side in 19 per cent of the patients. Volvulus of the sigmoid is discussed as a separate clinical entity. The value of x-ray diagnosis is emphasized by the authors. All of the patients with volvulus were treated by exteriorization and second stage resection. A mortality rate of 20.5 per cent is reported for all obstructions of the large bowel.

EDWARD F. LEWISON, M.D.

Studies on Experimentally Provoked Ileus with Reference to Inhalational Therapy.
Troell. *Acta chir. scand* 1947, 95, Supp. 133.

This experimental study of the diffusion of gases was predicated upon the clinical use of from 95 to 100 per cent oxygen inhalation in the treatment of ileus as worked out by Fine *et al.* in 1935 and upon the known toxic effects of oxygen when inhaled in high concentrations for a prolonged period of time. To avoid the toxic effect of the oxygen and at the same time procure the same beneficial effect upon the ileus helium in a mixture with oxygen was tested as an inhalant under varying circumstances. The effect of increased carbon dioxide concentration in the inhaled gas and of increased atmospheric pressure was also tested. In the second section of the experiment the known toxic effects of oxygen were reviewed and experiments were described which tested the effect of oxygen poisoning upon intestinal motility.

Intestinal gas diffusion was studied in experimentally provoked ileus in a series of rabbits. A quantity of 80 milliliters of nitrogen or helium was injected in closed intestinal loops of definite lengths and then the animals were placed in a 30 liter pressure chamber. Following a definite scheme the animals were allowed to breathe partly pure oxygen partly oxygen mixed with carbon dioxide, nitrogen, and helium in different concentrations and at 1 and 2 atmospheres of pressure. Three atmospheres of pressure were not used because the toxic effect of oxygen increases beyond reasonable clinical value at that pressure. On conclusion of the treatment the gas remaining in the intestinal loop was measured and its composition determined. The average was calculated in each series to determine the reduction in the total gas volume and also the reduction in the total gas specific gas injected into the loop of bowel.

The inhalation of 60 per cent oxygen and 40 per cent helium for 3 hours followed by the inhalation of 100 per cent oxygen and then of air for 1 hour each reduced the total volume of gas enclosed in the intestine slightly more than the inhalation of 100 per cent oxygen for 3 hours followed by the inhalation of

air for an hour. The diffusion of the helium injected at the beginning of the experiment increased by 5 per cent at the same time.

A carbon dioxide concentration of from 5 to 15 per cent in the inhalation gas increased the gas diffusion from the intestine approximately 6 per cent. An excess pressure of 2 atmospheres bringing the total pressure to 3 atmospheres increased the gas diffusion from the intestine by approximately 6 per cent as compared with similar inhalations at 2 atmospheres total pressure. When an increased carbon dioxide concentration in the inhaled gas was coupled with a pressure of 3 atmospheres, the gas diffusion from the intestine for a 4 hour period was increased by 12 to 13 per cent.

The toxic effect of oxygen on intestinal motility in vivo was studied in rabbits with the help of the abdominal window. As in the first part of the experiment, the animals were placed in the pressure chamber and allowed to breathe pure oxygen and oxygen mixed with carbon dioxide at 1 and 3 atmospheres of pressure according to a definite scheme. The rabbits were anesthetized with urethane during the experiment and a mirror placed in the chamber to observe the intestinal motility.

Continuous breathing of 100 per cent oxygen at 1 atmosphere of pressure produced slight to strong inhibition of motility in about 50 per cent of the cases in 4 to 5 hours, and no inhibition in other cases. At 3 atmospheres of pressure, 100 per cent oxygen produced moderate inhibition in all cases after 3 hours and almost complete inhibition in 6 hours. A partial pressure of from 4 to 8 per cent carbon dioxide had no effect upon the intestinal motility. The motility returned to normal following the oxygen inhalation in from 10 minutes to 3 hours when the rabbit was allowed to breathe air. The experiment indicated that inhibition of intestinal motility is a sign of oxygen poisoning.

The author feels that the results of the experiments support the opinion that 100 per cent oxygen treatment has an unsatisfactory effect upon the organism and that in cases of flous inhalation therapy with 100 per cent oxygen should be replaced by a combination method alternating 100 per cent oxygen with 60 per cent oxygen in helium. A carbon dioxide concentration of a low percentage has a favorable effect upon diffusion of gas from the intestine. When 3 atmospheres of pressure are used diffusion of gas from the intestine will be increased when 100 per cent oxygen is used as the inhalant.

In the treatment of flous the outlined therapy is of most value when treatment is instituted early and intraductal suction should be used simultaneously.

FREDERICK C. HOGGREN, M.D.

Chemical Investigation of Enteroliths in Greville's Case and the Report of a Further Case of Primary Calculus of the Small Intestine. Gunnar Bliz. *Acta. chir. scand.* 947 95 4 1

The author carried out a chemical analysis of the enterolith in a case reported by Greville. It was

found to consist of 70 per cent choleic acid, 6.6 per cent water, 3 per cent calcium oxalate, 1.6 per cent of fatty acids and cholesterol, 1.8 per cent ash (calcium and phosphate) and 10 per cent of bile pigments. Traces of iron and magnesium but no zinc, was present.

The author was sent a small intestinal calcareous diverticulum resected by Dr. J. Waldenström. The stone (weight 4 gm.) had a smooth, brownish-black surface layer 1 mm thick, with an interior of light brown. The center and the surface were analyzed separately. The interior was composed of calcium oxalate (56%), choleic acid (10%), fatty acid (8%), cholesterol (8%), water (3.6%), zinc sulphide (0.6%), the rest was composed of bilirubin calcium. The surface was composed of 70 per cent calcium oxalate, 4.6 per cent water, 4 per cent of substances soluble in organic solvents (fatty acids, cholesterol, choleic acid) the remainder being bilirubin calcium. No carbonate, magnesium phosphate or zinc was found, and only traces of phosphate were present in the stone.

In many ways this concretion had a similar chemical composition to that of the calculus previously reported by the author in 1935.

ROBERT K. BRIDLOW, M.D.

Benign Tumors of the Small Intestine (Finnish). *benign del. tenae*. T. Castrén. *Acta. Paediatrica, sc.* 1947 54 80.

The author presents 3 cases of benign tumors of the small bowel with a review of the literature. The first case presented symptoms of intestinal hemorrhage. The clinical diagnosis was that of duodenal ulcer with x-ray corroboration. At operation, the patient was found to have a deformed duodenal bulb, retracted and fixed so as to make resection impossible. A small tumor was also palpable about 10 cm. from the duodenojejunal angle. A posterior gastrotomy was performed with resection of about 5 cm. of small bowel and end-to-end anastomosis. The histological diagnosis was that of leiomyoma and because of its vascularity it was the author's opinion that the tumor was the source of the hemorrhage rather than the duodenal ulcer.

The other 2 cases were fibromas and both presented clinical pictures of obstruction. The first patient had repeated attacks and was operated on with lysis of adhesion. The author points out the danger of operating after repeated attacks before the patient has fully recovered from previous attacks. The second patient made an uneventful recovery. Both patients were found to have invagination of the bowel (intussusception) at operation. In the first case an end-to-end anastomosis was performed with resection of 30 cm. of bowel because of questionable vitality. The tumor was about the size of a pigeon's egg, and was located about 35 cm. from the ileocecal valve. The second case presented a fibroma, one the size of a small mandarin and the other the size of a large nut. About 1 meter of small bowel was resected and the

SURGERY OF THE ABDOMEN

tumors were located about 60 cm from the ligament of Treitz.

The author stresses the importance of keeping in mind the possibility that tumors may be the cause of small bowel obstruction when no other cause is apparent. He cites case reports in the literature in which the tumors were missed and the patients had to be operated on repeatedly. The possibility of repeated adenoma formation is mentioned and the case of Collier (*Med J Australia* 1927) is cited in which the patient with symptoms of bowel obstruction was operated on 3 times for adenoma of the small bowel and each time a tumor was found in a different part of the small intestine.

Use and Abuse of Intestinal Decompression Tube
A Study Based upon 288 Cases M O Cantor
A S Kennedy and R P Reynolds *Am J Surg.* 1947 73 437

The authors by means of a single lumen long intestinal decompression tube with a mercury balloon tip (the Cantor tube) have used intubation successfully in 96 per cent of 200 cases of intestinal distention. Technical emphasis is placed on understanding the mechanism of the tube. The propulsive mechanism is the head of the long intestinal tube which is a balloon tip filled with mercury. Should extravasation of mercury accidentally occur it is completely innocuous.

The only cases in which intestinal intubation alone can be safely used are those of adynamic obstruction or of inflammatory ileus.

All patients with mechanical ileus must be operated upon and intubation used as an adjunct prior to surgery. The use of the Cantor tube is recommended as a preliminary to bowel resection and the pa-

Intestinal intubation obviates the necessity for enterostomy and hence reduces the risk to the patient. It is suggested by the authors that the intestinal decompression tube is merely an instrument and that it must be used as such by the surgeon and not relegated to the intern or nurse. In the hands of a novice it may be harmful and dangerous.

The technique employed in successfully passing the Cantor tube is very carefully described and should prove helpful in mastering the simple tricks which have trapped so many surgeons so often.

Edward F Lennox 31 D
Nondrainage and Early Ambulation in Cases of Perforative Appendicitis Arnold S Jackson
Surgery 1947 34 644

The author presents 15 cases of perforative appendicitis with peritonitis or abscess formation in which the appendix was removed. Sulfathiazole was used intraperitoneally, closure without drainage was done and early ambulation encouraged. One case of secondary abscess required drainage. Otherwise there were no complications or deaths. From these instances the author concludes that nondrainage in cases of perforative appendicitis with

peritonitis is preferable to drainage. Such a procedure eliminates prolonged drainage and wound infection and minimizes the hazards of postoperative hernia, fistula, adhesions, etc. He advocates spinal anesthesia and early ambulation.

C. FREDERICK KITTLE, M D

Volvulus of the Cecum and Ascending Colon
Edward L. Young, Harvey R. Morrison and Walter E. Wilson Jr *N England J M* 1947 337 78.

The authors reported 7 cases of volvulus of the cecum and ascending colon which is of uncommon occurrence. Six patients were in the middle or elderly age groups. 2 patients had had more than one previous attack. 4 patients expelled flatus or other movements in spite of the volvulus at operation the cecum was frequently located in the left upper quadrant of the abdomen. The only death followed a resection and primary ileotransverse colostomy. These observations are in accord with those reported in the literature.

Volvulus of the cecum may be a congenital subacute or recurring. There is always a congenital lack of fixation of the cecum with a point of attachment below which the bowel rotates. In over 50 per cent of cases the cecum is mobile enough to allow the development of a volvulus and free enough to allow twisting are violent peristaltic forces that may produce torsion. The extraneous factors that may produce gastric or overeating abdominal tumors, mesenteric cysts, fecaliths, foreign bodies, direct violence, purulent constipation, acute appendicitis and pregnancy.

Although the correct diagnosis of acute volvulus of the cecum is usually not made before operation the authors believe that by careful roentgenologic study and a thorough review of the history and physical findings the diagnosis could be made oftener. The history is one of acute intestinal obstruction. In half of the cases there is a history of an antecedent colicky pain in the right lower quadrant of the abdomen with nausea and vomiting. The cardinal physical findings are distention, generalized tenderness and spasm of the abdominal muscles. Peristalsis is absent in the late cases. The pertinent roentgenologic points are dilatation of the cecum with variable lengths of the ascending colon and terminal ileum an abnormal position of the dilated cecum (in the left upper quadrant in 50 per cent of the cases), with absence of a normal cecal outline in its normal anatomic location and demonstration by barium enema of the twisting and torsion of the mucosal pattern at the point of lumen arrest characteristic of volvulus.

The treatment of acute cecal volvulus is early surgery because the longer the blood supply has been compromised the more radical the necessary surgery must be. The volvulus must be reduced, the obstruction must be relieved and recurrence prevented. The various surgical forms of therapy are (1) detorsion and resection resulting in cecal fixation to the anterior abdominal wall and decompression of the

bowel and (2) detorsion and resection of the cecum and ascending colon. If the viability of the cecum is in doubt resection of the cecum and ascending colon according to the Mikulicz technique and exteriorization should be performed. Postoperatively proper fluid and electrolyte balance and adequate nutrition should be maintained.

ROBERT TOWELL, M.D.

Wounds of the Colon and Rectum. J. E. Flynn
Am J Surg 1947 73 450.

The author discusses the high mortality and seriousness of wounds of the large intestine and rectum as evidenced by mortality statistics in World War I. Because of the better nutritional state of American soldiers in World War II the generous use of blood and plasma transfusions, chemotherapy and the benefits of early surgery it is suggested that death rates due to large bowel wounds will be considerably lower in the final reckoning of World War II.

Types of injury to the rectum and large bowel are described and the character of lesions in different parts of the colon are discussed and illustrated by case reports.

Experience in World War II has repeatedly demonstrated the wisdom of treating wounds of the colon by exteriorization whenever possible. If primary closure is ever performed then a proximal colostomy is to be an adjunct procedure. Resection is rarely indicated in wounds of the large bowel.

When a colostomy is performed the two ends of the bowel should be completely transected and both ends of the bowel brought out on the abdominal wall at different sites. This procedure prevents spillage of fecal material into the distal loop, prevents intestinal obstruction, prevents interposition of a loop of small bowel in a septum and permits an easier end-to-end anastomosis in final closure.

A Mikulicz colostomy was commonly used by front line surgeons during the early part of the war. In most of these cases it was found feasible by the author to close the spur by a crushing technique. However in 20 per cent it was found necessary to perform an intraperitoneal end-to-end anastomosis. The author suggests the advantages to be gained by a Devine type colostomy.

The problem of edema of the colostomy stoma or exteriorized wounded segment of large bowel is discussed and satisfactory treatment by pressure is described.

The very important point of not making a colostomy stoma through the exploratory laparotomy incision because of sepsis and dehiscence is emphasized.

The special problem of rectal wounds and their treatment by nonsuture but proximal colostomy is presented. The period of waiting for spontaneous wound closure, as proved by x rays and proctoscopy before colostomy closure is most important, particularly in the definitive stage of surgical repair. Skillful surgery at advance installations was one of the real advances in World War II.

EDWARD F. LEWIS, M.D.

Perforations from Proctoscopy. Albert F. R. Kahn
Gastroenterology 1947 9 32.

Of 340 questionnaires a king for reports of cecal perforation as a result of proctoscopy which were sent out to every member of the American Gastroenterological Association and the American Proctologic Society 215 answers were received. One hundred and thirty-eight members replied that they had encountered no perforations. 45 reported 1 perforation from other causes than proctoscopy, 34 reported 46 cases of perforation due to proctoscopy. In addition 48 cases of proctoscopic perforation were collected from the literature.

The serious nature of the injury is evident. Of total of 94 cases of proctoscopic perforation of the rectum or sigmoid there were 45 deaths—a mortality of 47 per cent.

Early diagnosis is important, and immediate operation is indicated. The mortality of cases in which the perforation was recognized at once and in which immediate operation took place was 8 per cent. Operation in the period of 3 to 6 hours after perforation bore a mortality of 50 per cent and in the 6 to 12 hour period there was a death rate of 75 per cent. Shock and sudden severe abdominal pain are characteristic diagnostic points when they occur. In these symptoms were seen in less than half the cases. In the majority of instances the perforation was recognized at proctoscopy when the instrument was suddenly felt to pass "higher than usual," or when bowel rent, fat peritoneum or abdominal contents were visualized through the proctoscope. Signs of peritoneal irritation may occur immediately but frequently these are delayed until the development of a true peritonitis. The roentgenologic finding of gas under the right diaphragm is pathognomonic of perforation of a hollow viscus, and may be required for an adequate diagnosis. A rising leucocyte count and a rapidly increasing sedimentation rate are constant findings.

The authors conclude that although proctoscopy is a valuable diagnostic aid it is not unattended by danger and should not be performed by those who have not adequate training in the technique. At all times the instrument should be passed under direct visual guidance, and where this last is not possible owing to persistent angulations of the bowel, fecal accumulations, bloody or other discharge, the presence of new growths, or to the struggles of a nervous, unco-operative patient, the examination should be immediately terminated.

Comprehensive statistics showing the reason for examination, the cause of perforation, concomitant disease and the type of operation performed, as well as suggestions for preoperative and postoperative care are included.

WAYNE CAMBROW, M.D.

Right-Sided Colitis. Burrill B. Crohn, John H. Garlock, and Harry Yarnis. *J Am Med Ass* 1947 34 334.

The colon on the right side is the site of nonspecific ulcerative colitis in 8 per cent of the cases of this

condition. The condition cannot be diagnosed by sigmoidoscopic examination. Later in the disease there may be a patchy or continuous extension to the remainder of the colon. In contrast to colitis on the left side, there are less of the classical symptoms such as diarrhea, urgency, and bloody stools, but more constitutional manifestations such as fever, joint pains, ocular complications, and involvement of the heart.

The authors have studied 77 cases of colitis on the right side. No specific organisms have been implicated. The average age of the patients has been 27.3 years; the youngest being 6 and the oldest 60. There were 45 women and 32 men.

The authors observed that while the rectum and anus were not involved by the inflammatory process, perirectal abscesses and fistulas were present. The assumption is that the infectious agent is carried from the right colon to the crypts of Morgagni and leads to infection, abscesses, and fistulas.

Forty nine of 77 cases showed fevers ranging from 101 to 105 degrees. The leucocyte count was usually low or only slightly elevated (8,000 to 15,000). Diarrhea was minimal. One or more joints were the site of periarthritic inflammation. Phlyctenular conjunctivitis, iritis, keratitis, and uveitis were not common but did occur.

Medical management consists of 350 c.c. retention enemas of a 1 to 4000 solution of neutral acriflavine in saline solution daily. Insoluble sulfonamides in doses of 0.55 gm. per kilogram of body weight daily and intramuscular injections of crude liver extract and vitamin B complex.

On the basis of their experiences the authors believe that most of the patients will require surgery. In many cases the disease progresses from right to left and eventually involves the rectum.

When there is evidence of involvement of the sigmoid or rectum, the first operation should consist of ileostomy followed from 3 to 6 months later by subtotal colectomy. After the seriously diseased colon is removed, the rectum returns to normal and it is possible to reconnect the ileum and the upper part of the rectum.

When the rectum and sigmoid are not involved the first operation is carried out through a left rectus incision. The terminal part of the ileum is divided about 8 inches from the cecum after section of its mesentery and accurate ligation of the vascular arches. The proximal loop should be well mobilized so that it can be anastomosed to the rectum deep in the pelvis if necessary. Both ends of the ileum are simply inverted with silk and the distal one is dropped into the abdomen.

The colon and mesocolon are divided at a healthy point. The proximal part of the colon is brought out through the abdominal wall for externalization to allow for external drainage of the foul discharge that comes from the diseased segment. The distal end of the colon is now inverted with three layers of silk. The proximal ileac loop and distal colon are connected by a side to side anastomosis.

The second operation, which is a subtotal colectomy is done through a right rectus incision when the patient has sufficiently recovered.

DANIEL RUOZ, M.D.

The Importance of Malignant Degeneration as a Complication of Chronic Ulcerative Colitis.
Richard B. Catroff and Earl J. Boehme. *Gastroenterology* 1947 8: 695

In the present article, the importance of malignant degeneration as a complication of chronic ulcerative colitis is emphasized. The authors review approximately 75 cases from the literature. Nine additional cases are reported. Carcinoma arising from ulcerative colitis is highly malignant and metastasizes early. Few patients have had resections and only an occasional one has survived as long as 5 years. All patients with long-standing ulcerative colitis should be examined at frequent intervals as a means of early discovery of malignant disease. This offers the only hope of improving the present unfavorable results.

The comparatively few cases of carcinoma complicating ulcerative colitis (approximately 75) appearing in the literature do not give a true picture of the prevalence of this complication. There are several reasons for this: the chief of which is that long follow-up studies must be made.

In the present series the average duration from the onset of ulcerative colitis until the development of the cancer was over 9 years. In a series of 54 cases reported by Bergen and Sauer it was 17.6 years. During such a long interval many cases are not traceable. It is also probable that some patients die of carcinoma when the ulcerative colitis is in complete remission, and the death is not associated with the previous ulcerative colitis or death is assumed to have occurred as the result of reactivation of the colitis. Other follow-up studies are of insufficient duration to be significant. A second factor in this apparent paucity of cases may be that in most cases the patients are not operated on. In some of the cases reported the cancers have been found during colectomy and if the indications for resection were broadened the incidence of carcinoma discovered might well be increased. In addition it is probable that some of the patients who died with ulcerative colitis, without autopsy had malignancy as the cause of death. Finally a careful pathologic study should be made of colons removed at operation or autopsy. Many of the lesions are small, and if there is extensive polyps or pseudopolyps, careful search may reveal lesions in the bowel wall or in the polyps.

Ulcerative colitis developing in children should be watched with great care since in them the incidence of cancer is so high. Early colectomy might prevent some of the deaths in these cases. The rectum and sigmoid should be inspected periodically in all cases of long-standing ulcerative colitis in which an indication for colectomy has not arisen. Any colon defunctionalized by ileostomy should be studied by

barium enema periodically to rule out malignancy in the part of the colon not visualized by sigmoidoscopy. It is also evident that in the so-called cured cases of ulcerative colitis a periodic roentgenographic and sigmoidoscopic study of the patient's colon should be made throughout life.

CHARLES BARON, MD

Cancer of the Colon and a Detail of Operative Technique. Rudolf Brandberg and Tore Ekblom. *Acta. chir. scand.* 1947 95: 461.

The literature indicates a 'palpable' improvement in the results of the treatment of cancer of the colon during the past decade. There has been a numerical increase in operable cases and a reduction in operative mortality.

No such progress has been made among the 107 patients with colonic cancer hospitalized from 1940 to 1946 in the authors' care (nor indeed in Sweden). This is due largely to the condition in which the authors' patients were received: 29 had acute ileus, 33 had chronic obstruction, and the average age was high, 70 per cent of the patients being over 60 years and 30 per cent over 70 years of age.

Some type of resection was carried out in 63 cases—an operability rate of 59 per cent. Ochsner and DeBakey's series of 4,561 cases had an operability rate of 58.5 per cent. (In Zininger's series [1943] among private patients the operability rate was 91 per cent among charity patients, 52 per cent.)

In the authors' cases, the primary mortality was 13 per cent. The total death rate following resections for tumors on the right was 19 per cent and for tumors on the left, 10 per cent. This is the reverse of the usually reported higher mortality for left-sided tumor resections. (Ochsner and DeBakey [1939] give mortality rates of 10.6 per cent for right-sided and 24.4 per cent for left-sided tumors with a total mortality of 31.7 per cent.)

The author's follow-up studies on various types of resection yield no conclusive evidence in favor of any individual procedure.

FRANK B. QUEEN, MD

The Surgical Treatment of Cancer of the Rectum and of the Sigmoid. (Tratamiento quirúrgico del cáncer del recto y sigmoides.) J. Iglesias de la Torre and E. Figuera Campos. *Rev. med. cubana* 1946, Vol. 57.

The authors recommend abdominal perineal resection in one stage as the elective surgical treatment of rectosigmoid cancer. The invasion of this type of tumor is discussed and the symptoms which should lead to the early diagnosis of this lesion are enumerated. Distal rectal examination and rectosigmoidoscopy including the biopsy of lesions are considered of major importance in the early detection of these tumors. The formation of an ileac anus is considered the elective procedure, the perineal colostomy being a more difficult procedure and leading to subsequent stenosis of the bowel.

In cases of cancer of the rectosigmoid with intestinal obstruction the Devine colostomy is advised.

Wide resections are advised including the rectum, the anus and its sphincter, the levator ani muscles, the ischio-rectal fat, the mesosigmoid, and the pelvic peritoneum. Catheterization of the ureters is considered imperative. The authors emphasize the importance of suturing the free mesosigmoid to the colostomy to the lateral wall of the abdomen to avoid herniation. The Sims position for the postoperative stage is considered elective.

WILLIAM E. RICEHILL, MD

Resection of the Rectum and Rectosigmoid with Primary Extraperitoneal End-to-End Open Anastomosis. Carleton Mathewson, Jr. and Victor Richards. *West J. Surg.* 1947 57: 67.

For more than a century surgeons have prepared various procedures for preserving the sphincter anismus following resection of carcinoma of the rectum and rectosigmoid. Because of the high mortality and morbidity associated with the earlier attempts because of the fear of local recurrence most of these methods were abandoned in favor of abdominal local resection. Newer studies on lymphatic spread together with our present knowledge of the means of controlling infection following intestinal surgery, have led to renewed efforts on the part of many surgeons to avoid permanent colostomy. The safety and adequacy of procedures directed toward restoration of the normal course and control of intestinal erosion have recently been made evident.

Although occasionally of high grade malignant most carcinomas of the rectum and rectosigmoid are known to be relatively slow growing; hence, it would expect considerable local growth before widespread metastases occur.

During a 2 1/2 year period up to January 1947 the authors have performed 29 consecutive resections of the upper rectum and rectosigmoid with primary end-to-end anastomosis without a single hospital death. The procedure was carried out as a palliative measure in 6 patients and with the hope of a cure in 23 patients. Preoperative preparation included adequate use of succinylsulfathiazole. Preliminary transverse colostomy was used in the presence of obstruction but not as a routine adjunct. Postoperative care included the use of blood fluids, and acids, penicillin and sulfonamides.

The authors state that the method is simpler than the closed method, the blood supply is better preserved and there is freedom from postoperative complications. No fecal fistulas have developed and all patients have maintained bowel control.

HARRY W. FINE, MD

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

The Pathogenesis and Different Forms of Jaundice. Torben K. With. *Acta. med. scand.* 1947, 18: 5.

Because of the numerous modifications of the theories published by Rich. in 1930, concerning the

pathogenesis of jaundice the author presents a review of the subject.

Jaundice is a yellow coloring of the skin which occurs simultaneously with hyperbilirubinemia. The plasma or serum threshold for jaundice in white adults is 15 to 20 mgm. per 100 ml. In babies it is 8 to 9 mgm. per 100 ml. It is believed that some responsible for the yellow color of plasma are rubin hifuscin, and mesobilifuscin.

The yellow color of the organs is due primarily to the deposition of yellow substances in the tissues and the yellow color of the circulating plasma plays only a minor role. It is evident that bilirubin does not enter the tissues by diffusion from the blood plasma into the tissue fluid. This is improbable since the bilirubin is firmly bound to albumen in the serum also when deposited in the tissues bilirubin is firmly bound to elastin. The combination therefore is responsible for the yellow color. The fate of bilirubin in jaundiced organs is unknown. In longstanding jaundice decomposition takes place but in the absence of chemical analyses of jaundiced skin this question cannot be settled.

The author believes that Rich's classification of jaundice will have to be revised as it is based on the behavior of the diazo reaction.

The author classifies jaundice into three forms

- (1) Production jaundice caused exclusively by increased bilirubin production
- (2) Retention jaundice, caused by the retention of bilirubin in the blood because of deficient liver function
- (3) Lymphogenous jaundice caused exclusively by the flow of bilirubin into the lymph spaces of the liver

These forms of jaundice are rarely found alone and they combine to account for the known clinical forms of jaundice.

Hemolytic jaundice production plus retention jaundice

Parenchymatous jaundice (hepatitis) lymphogenous (regurgitation) plus retention jaundice

Occlusive jaundice lymphogenous (abnormal secretion) plus retention jaundice

Icterus neonatorum lymphogenous (abnormal secretion) plus probably production jaundice

The lymphogenous jaundice in occlusive jaundice and icterus neonatorum is suggested to be due to a special secretory mechanism from the blood capillaries into the lymph spaces of the liver while in parenchymatous jaundice it is due to regurgitation into the lymph spaces opened by necrotic processes in the parenchyma.

The author suggests that the absence of bilirubin in the urine in hemolytic jaundice is a factor only of the low serum bilirubin level and has nothing to do with the diazo reaction.

Several possible explanations are given for the early bilirubinuria which precedes clinical jaundice. The problem of urobilinuria preceding bilirubinuria is discussed.

ROBERT R. BICKLOW M D

A Contribution to the Study of Epithelial Cysts of the Liver (Contributo allo studio delle cisti epiteliali del fegato) Silvio Flamini Arch. ital. chi. 1946 68 435

The author presents a case of epithelial cyst diagnosed preoperatively as hydrops of the gall bladder with atones and presents a review of the literature with various classifications of hepatic cysts. He believes that the cysts are due to inclusion of embryonal germ tissue derived from the cystic outline of the hepatic parenchyma. A comparison is made with polycystic kidney.

Up to 1938 about 100 cases had been reported. These cysts are much more frequent in women than in men. Various reports listing the ratio to males as 98 to 22 (Lenormant) and 17 to 8 (Mayo and Harrington). The ages at which it is commonly encountered lie between 40 and 50 years. However in most cases the condition had existed for many years before it was diagnosed at autopsy or operation.

The cysts are more frequently found in the right lobe of the liver. The findings may vary from single cysts to a polycystic liver. The evolution is gradual and there is a tendency of the cysts to grow toward the peritoneal cavity. The gross appearance is that of a rounded, smooth shiny cystic mass often transparent but usually tendinous in appearance. The masses are usually imbedded in the parenchyma and are pedunculated but very rarely. Sometimes they are arising from hepatic transplants are mentioned such as the case reported by Mayo with the cyst arising in the round ligament. The cavity is usually single but may be multilocular. The content is usually a lemon colored liquid varying in density from 1005 to 1025 with a neutral or alkaline reaction a high albumin content 4.5 per cent and more chlorides from 6 to 8 per cent, and usually no bile pigment. The content is usually sterile few cases being reported with infection. Microscopic study usually revealed some blood cells, hepatic cells and almost always cholesterol crystals.

The dimensions vary from that of a chick pea to one containing 9 liters. Symptoms vary and are usually due to pressure on the adjacent structures. Pain is not characteristic and is considered to be due to stretching of the visceral peritoneum with no relation to meals. The first symptom is usually that of noting a tumor in the right upper quadrant. Jaundice is usually not present.

The differential diagnosis is given in detail but is essentially that of a mass in the upper abdomen. Among the complications are hemorrhage, torsion, and rupture. Infection is rare and has been found only in patients who had been punctured for diagnostic purposes. In short, spontaneous infection of the cysts has not been recorded.

Therapy is essentially surgical in nature. The author recommends excision when possible, either enucleation of the cyst or resection with adjoining liver tissue. In the case reported the cyst itself was enucleated with ease and bleeding was easily controlled.

trolled with catgut sutures. Difficult cases have been marsupialized, but this prolongs the cure.

LOUISE J. FROSTOTT M.D.

Results in Gall Bladder Surgery Leonard W. Edwards and Charles K. Gardner *South. Surgeon*, 947 13 480.

The present article deals with some of the details which are important in gall bladder surgery and the authors give a summary of the results they personally obtained with operation in 200 cases of non-malignant biliary tract disease as encountered at the St. Thomas Hospital Nashville, Tennessee, from 1937 to 1947.

From the surgical standpoint, it is well to regard stone formation as a part of cholecystitis. It is well known that removal of nonstone containing gall bladders frequently results in failure to relieve symptoms, while removal of gall bladders containing stones usually results in cures. The high percentage of acute cholecystitis associated with cholelithiasis generally needs no further elaboration. A series of 18 acute cases showed 27 with stones, 96.4 per cent the overall series showed the presence of stones in 187 cases, or 93 per cent.

Just as most cases of cholecystitis deserving of operation will be accompanied by stones, so will most cholecystitis deserving of operation show either stones or a nonfunctioning gall bladder by properly performed and properly interpreted x-ray studies. Unless clinical evidence is strongly indicative of cholecystitis, a single x-ray report of a nonvisualizing gall bladder should be checked by repeating the x-ray studies.

It is becoming evident that fundamentally cholecystitis is a metabolic disease in which chemical and mechanical factors combine to produce repeated acute attacks characterized by vascular changes in the gall bladder. These vascular changes vary from mild congestion to gangrene. The process is a progressive one so that the risk and mortality in cholecystitis roughly parallels its duration being noticeably higher in persons past 50 years of age.

When bacterial infection is present in cholecystitis, it is a secondary process to metabolic, chemical and vascular changes. This concept of the disease is not unimpaired of infection but it leads the surgeon to realize that if the gall bladder is removed early in the acute attack infection will have had less time to develop. Danger of operation will be correspondingly less. Most patients are not seen by a surgeon at the onset of the acute attack, due to uncertainty of diagnosis and delay by medical doctors.

The patient with acute cholecystitis should be admitted to the hospital as soon as the attack occurs. An appraisal of the patient's physiologic and operative condition should be made on admission, and operation should be performed as soon as the patient is properly prepared. Usually this should be possible within 24 hours. Careful clinical observation should be made frequently in order to evaluate the course of the disease.

Laboratory procedures take second place to clinical observation and include blood amylase, albumin-globulin ratio, prothrombin level, nonprotein nitrogen, icteric index and liver function tests. Wengensteen suction is indicated if abdominal distention is marked. Intravenous glucose and amino acids should be given as indicated to overcome dehydration, protein deficiency and diminished liver function. In jaundiced patients, parenteral injection of vitamin K and repeated blood transfusions are indicated to overcome bleeding tendencies due to hypoprothrombinemia. Prompt administration of penicillin or other drugs may be indicated to combat or to prevent infectious complications.

Unless the patient is seen in the first 24 hours after onset of the attack, preparation for surgery can rarely be accomplished in less than 12 to 24 hours. Although many acute attacks might be delayed several days with safety the observation has frequently been made that often there is little correlation between the clinical severity of acute cholecystitis and the pathologic changes actually taking place in the gall bladder. Some apparently mildly acute cases perforate without warning. This bears out the need for delay only until the patient is in a satisfactory physiologic condition for operation.

The acutely ill, jaundiced patient with gallstone obstruction presents the most difficult problem. The most dependable sign of a progressive process with impending perforation is continued or increasing abdominal pain and rigidity.

From a technical standpoint, there are several details worthy of attention. Whatever incision is used it is advisable to obtain adequate exposure so as to visualize the structures about the common duct. The transverse incision has the advantage of less postoperative pain and fewer wound disruptions.

The incision may be made across one or both rectus muscles as indicated for good exposure. Careful closure of the transversalis fascia and peritoneum lessens the incidence of wound disruption and hernia.

The authors prefer to expose the common duct, cystic duct and cystic vessels by blunt dissection, and to remove the gall bladder from below. They point out that the danger of injury to the bile ducts and right hepatic duct has been stressed too little.

Postoperative care of patients with gall bladder disease should follow the same principles as those used in preparing the patient for surgery. Early moving in bed and early walking help prevent pulmonary complications. BENJAMIN GOLDMAN M.D.

The Persistence of Symptoms Following Cholecystectomy Nathan A. Wornack and Russell L. Ordor *Ann Surg* 947 126 3

Clinical and experimental evidence obtained from observations on both animals and man shows that stimulation of the nerves distributed along the common and cystic ducts results in symptoms identical with those occurring in biliary tract disease. It is not the persistence of a large cystic duct, per se,

SURGERY OF THE ABDOMEN

59

that results in the presence of symptoms of biliary tract disease after cholecystectomy but rather the inclusion in the scarred walls of the duct of bundles of nerve fibers chiefly sympathetic in type, with perhaps a smaller number of vagal fibers. At times fibrous tissue proliferation in type, with peritoneal form of amputation neuroma. Since both the anterior and posterior plexus tend to converge in the region of the cystic duct, it is sometimes easy to include many of these fibers in the ligature about the cystic duct. In such cases there may not be true neuroma formation, but rather a constriction and ischemia of the nerve fibers in a region subject to variation in intraductal tensions during the day. Another type of lesion found in the nerve plexus results from the laying down of a diffuse sheath of dense fibrous tissue over the anterior surface of the common duct, in the region of the stump of the cystic duct. When this is examined microscopically it shows the same type of nerve trunks encased in scar tissue.

The presence of scar tissue around nerve trunks produces stretching of the fibers and ischemia. Both of these factors lower the threshold of stimulation of nerve endings and nerve trunks. The presence of the damage found in these cases, therefore, makes the nerve fibers more susceptible to stimulation so that a mild stimulus, normally almost imperceptible may produce a very marked effect. The position of the ducts about the expanding and contracting common duct, and occasionally the contracting common duct, and the expanding and contracting common duct, is also a factor in the production of these postcholecystectomy symptoms several months after the operation.

As a rule, after cholecystectomy several months elapse before the recurrence of symptoms. This is in keeping with the time required for the laying down of the dense collagenous scar. In many instances after the lapse of several years symptoms disappear and complete degeneration of the damaged nerve trunks.

In order to prevent the appearance of these postcholecystectomy symptoms it is advisable whenever possible to separate the nerve trunks mesial to the common bile duct. In most cases this is easily done if the peritoneum and underlying areolar tissue are removed from over the common duct before the gall bladder is resected. The nerve trunks are then well visualized. Should such treatment of the common duct appear to be dangerous it is best to strip completely the cystic duct of all its adjacent structures as well as the cystic artery. In this way none of the nerve fibers is caught in the ligature.

A similar procedure is carried out in those patients who have to be operated on for the so-called postcholecystectomy syndrome. The stump of the cystic duct is removed close to the common duct. Any scar on the surface of the common duct is carefully removed. The nerve trunks as a rule thus become well visualized on the mesial side of the common duct, and can likewise be destroyed.

SAMUEL KATZ M.D.

Disease of the Cystic Duct. Stasis of the Bile in the Gall Bladder Due to Hypertonicity and, Eventually, Sclerosis of the Sphincter of Oddi. (La maladie du cystique. Stases vésiculaires per de Luthens) P. Mallet-Guy R. Jeanjean and J. Ferroldi *Lyon chir.* 1947 41 174.

In the pseudobiliary pain syndrome treatment by routine cholecystectomy or cholecystogastrostomy although undeniably giving many successful results is not to be condoned. In these dilated gall bladders which otherwise seem to be normal and for which surgery is indicated as a result of the failure of medical measures the authors have been injecting fluid (water) into the exposed gall bladder and overcoming the resistance of water pressure necessary to passage of the fluid. Where the curve of the cystic duct to the manometer has risen steeply to 15 or 50 cm in the pressure of the fluid. The curve of the water enough a cystic block has been diagnosed and a cholecystectomy performed. The stump of the cystic duct is then catheterized and a control radiograph is made to determine the permeability of the sphincter of Oddi. In the presence of resistance of the sphincter a transduodenal sphincter may be accomplished at this or at a secondary operation. In the present series, a cholecystogastrostomy was done only once and this with discouraging results. Some operations on the sphincter and vagus nerve were carried out but the number of cases was too few for any idea to be gained of the efficacy of the procedure.

As regards the results obtained with cholecystectomy alone in 8 cases the results were excellent for the time the patients were observed. In 12 other patients the results were imperfect, but the improvement was estimated at about 50 per cent by the patients themselves. In 1 patient the painful attacks reappeared but could be largely controlled by the patient (beta-phenylisopropylamine). Finally in 9 other patients a follow-up has been impossible because the patients themselves report that their pain, attacks and functional disturbances have been entirely relieved.

The authors believe that cholecystectomy is an efficacious method of treatment of "disease of the cystic" when surgery is indicated however it is not to be done without preliminary assessment of the functional condition of the principal bile duct, as difficult as this assessment may at times prove to be.

MISCELLANEOUS

Surgical Aspects of Amebiasis. P. Theron. *Brit. M. J.* 1947 2 133.

During the recent war amebic colitis was so prevalent that it constituted a major problem for the medical services. Of greater importance however was the disturbingly high relapse rate after treatment. It seems likely therefore that the complications of amebic dysentery will play an important

part in post war civilian practice. In the surgical sphere an infection of this type is apt to give rise to considerable difficulty in diagnosis, and may at the same time exert a great influence on the course and outcome of surgical ailments and in particular on the results of operative treatment.

The mortality rate following operations on patients suffering from untreated and often undiagnosed amebic infection is considerable. This is largely explained by

- 1 The reduced resistance as a result of the chronic infection with consequent increase in the number and severity of postoperative complications. A factor of importance is the frequent association of hypoproteinemia with amebic infection (Faust 1930 Elsdon Dew 1946). The predisposition towards the development of postoperative complications caused by this type of deficiency is too well known to require amplification.

- 2 The interference with wound healing with the occurrence in some cases of ulceration and sloughing of the skin of the abdominal wall. This complication is especially apt to occur after the establishment of a colostomy.

- 3 The tendency to breakdown at the suture line after operative intervention on the bowel. Consequently procedures such as intestinal anastomosis, appendicectomy etc. may be associated with the development of fecal fistulas and general peritonitis.

- 4 The development of acute amebic dysentery during the immediate postoperative period—probably the result of handling of the bowel during opera-

tion. In most cases this is of little moment, provided that early treatment is instituted. On occasion, however, the condition may simulate bacillary dysentery in the severity of the diarrhea with a consequent adverse effect on the prognosis. It is of interest that this phase of acute diarrhea may occur within 48 hours of operation in patients suffering from severe general peritonitis. This was a feature in 3 cases in which the development of paralytic ileus had appeared almost inevitable. Stool examination revealed the presence of numerous free forms of *Entamoeba histolytica* with ingested erythrocytes.

- 5 During the postoperative period a mild hepatitis is not uncommon. Spontaneous remission is usual but occasionally a progressive form is encountered. Many of these postoperative complications are likely to occur in Britain during the post war years. Failure to recognize the cause may be disastrous. Thus it would be good policy to view with suspicion every candidate for operation who has seen service in a tropical or subtropical zone, whether or not a history of dysentery is elicited and, where possible, preoperative investigation in the form of sigmoidoscopy and stool examination should be employed. After emergency operations a watchful eye should be kept for complications suggestive of amebiasis, so that early and energetic treatment may be instituted if necessary.

The results are given in a series of cases which include infection of the liver, perforation of the colon, acute infection of the caecum, and intestinal obstruction due to amebiasis.

CHARLES BARON, M.D.

GYNECOLOGY

ADNEXAL AND PERIUTERINE CONDITIONS

Meigs's Syndrome; A Case Report and a Review of Recently Published Cases Herbert J. Simon
Am J Obst., 1947 53 1042

The author reports a case of Meigs's syndrome from the City Hospital, New York, New York. He also tabulates a synopsis of 17 additional cases that have been published recently which brings the number of reported cases of this syndrome to 44. The patient was a 55 year old woman who appeared to be in a hopeless condition. The significant findings were a bilateral hydrothorax that filled the right side of the chest, a large abdominal tumor the size of a full term pregnancy and associated with ascites and a tremendous femoral hernia that extended from the right inguinal area to the knee. Twenty five hundred cubic centimeters of serous fluid were removed from the right chest and on the following day a large smooth firm and round tumor of the right ovary about 27 cm in diameter was removed. The patient made a rapid convalescence and was in good health 9 months later. The tumor was a fibroma of the ovary.

The importance of giving every patient who presents the triad of tumor, ascites, and hydrothorax the benefit of operative exploration is emphasized. This is true no matter how hopeless the condition of the patient appears on the first examination. Many patients with this syndrome are in all probability being overlooked.

JOHN R. WOLFE, M.D.

Granuloma of the Fallopian Tube Due to Surgical Glove Talc. G. B. S. Roberts. *Brit J Surg* 1947 34 417

Seven cases of silicious granuloma are described 2 occurring in appendectomy scars and 5 in the fallopian tubes.

A historical review and case reports are given. The lesion occurring in a scar wound was characterized by the development of a mass in the scar of a previous operation wound with moderate pain or discomfort at this site. A differential clinical diagnosis must be made from a keloid which generally develops within a year of operation.

All 5 patients with lesions in the fallopian tubes had undergone a previous laparotomy for appendectomy and, apart from 1 who had an abortion the patients were all sterile. The symptoms were suggestive of a low grade pelvic inflammation and physical examination revealed thickened tender fallopian tubes.

Microscopy revealed the presence in all the lesions of doubly refractive material, this was considered to be talc deposited at the earlier operation. A differential diagnosis from tuberculosis of the tube especially the proliferate form had to be made. It would seem reasonable in the microscopic examination

tion of the pathological fallopian tube to accept as primarily silicious a giant cell granulomatous reaction with scanty or absent endothelioid cells without caseation and presenting doubly refractive material within or closely related to the giant cells.

The lesions produced by the introduction of talc into the tissues or body spaces probably are more common than is generally believed. Treatment is prophylactic. When once the silicious particles are deposited it is improbable that surgical treatment could prevent the ultimate occlusion functional if not organic of the fallopian tubes.

Diverticulitis of the Colon in Gynecology Edward Allen and L. Bruce Donaldson. *West J Surg* 1947 55 393

Diverticulitis of the colon is a frequent disease of middle and old age. It is more common in the female than in the male. Because of the symptomatology of the disease a gynecologist is frequently consulted. Since 1934 362 patients with diverticulitis have been admitted to the Presbyterian Hospital in Chicago. Of these 223 were females 59 of whom were seen in consultation with or were treated by members of the gynecological staff. The series of 59 cases is presented.

In the present study colon diverticulitis has been found to be a frequent cause of left lower quadrant pain, bladder irritation, and pelvic mass formation. The authors urge that any patient with this clinical picture particularly if she be over 35 years of age, be thoroughly investigated by roentgenography and stool examination before surgery is undertaken. Barium enema and a roentgenogram of the colon make the best single diagnostic facility. The characteristic film in colon diverticulitis reveals saw toothed serrations with a long bowel segment. There is evidence of break in the bowel continuity. Fluoroscopic examination may add valuable information. The sigmoidoscope will prove of value in establishing the diagnosis in a high proportion of cases but examination is believed to be of no value. Stool examination is recommended primarily to rule out amebiasis.

The predominant symptoms of chronic constipation, diarrhea, gas formation (abdominal distention, belching and flatulence) and abdominal pain point of course to a disturbance in the gastrointestinal tract. On the other hand abdominal pain and the frequent complaints of backache, bladder disturbances, fever and the presence of an abdominal mass point rather to a localized pelvic disorder. In this series, for example the gynecologist's diagnosis was cystitis in 4 patients with diverticulitis of the colon who had severe bladder complaints. These symp-

INTERNATIONAL ABSTRACTS OF SURGERY

toms are frequently present when adhesions or infected diverticula impend on the bladder. Other mistaken diagnoses made in the series presented were as follows: pelvic inflammatory disease in 8, ovarian cyst in 5, uterine fibroids in 8, pregnancy (tubal and intrauterine) in 3, and ureteral stone in 3.

The authors stress the fact that if the patient is thoroughly studied the diagnosis of diverticulitis of the colon can be made and the patient properly treated. The palpatory pelvic findings of a tender, fixed, leavlike mass flowing out from the region of the sigmoid colon plus careful roentgen examination of the bowel should save many patients needless laparotomies.

L. JAMES TALBOT, MD

Surgical Care of Urinary Incontinence in Women

R. W. To Lindo. *Ann. Surg.* 1947 126 64.

The author observes that incontinence of urine in varying degrees in women is one of the common complaints heard in every gynecologic clinic. When the symptom is of a marked degree there is nothing more distressing to the patient. Not only is there the physical discomfort associated with constant moist

and local irritation but there is an unmistakable odor of decomposing urine which is annoying to the patient and those in proximity to her.

In general surgical results to cure this condition are not as satisfactory as they should be. This is shown by the great number of women who seek relief at the larger clinics, after undergoing previous unsuccessful operations. Of the many reasons for these failures one of the principal ones is the lack of knowledge of the exact anatomy of the parts and the failure to know completely the physiology of micturition. Another is the lack of training in female urology of surgeons, gynecologists, and obstetricians who attempt plastic operations to restore continence. The author's experiences of the past decade are reviewed in the article presented.

The types of incontinence considered in this series are summarized as follows:

1. Stress incontinence of different degrees, varying from slight, occasional loss of control on severe straining at coughing, sneezing, or lifting heavy weights to almost complete incontinence which occurs with the slightest exertion. Stress incontinence is usually associated with cystourethrocele, with or without uterine prolapse. Occasionally this condition is seen without these conditions and even in nulliparous (usually elderly) women.
2. Vesicovaginal fistulas due to childbirth injuries, surgical injuries and destruction of the vaginal and bladder walls by malignant disease of the pelvic organs and/or irradiation therapy.
3. Defects in the urethra and sphincter, due to congenital defects, obstetrical and surgical accidents, or destruction by malignancy or lymphoplasia retroperitoneum.
4. Incontinence due to neurologic disease, such as spina bifida, multiple sclerosis, or tabes dorsalis.
5. Ureterovaginal fistulas due to operative or radiation injuries.
6. Inflammatory lesions of the urinary tract, causing such marked frequency and urgency as to result in practical incontinence. This type is not included in this series but it is important that it be recognized and differentiated from those types in which there is

Fig 3

a defect in the sphincter mechanism or bladder or ureteral walls.

Stress incontinence is many times more frequent than all of the other types combined. It is the simplest type to cure surgically and yet results are not uniformly satisfactory. During the past 10 years, 249 operations for stress incontinence were done on the Gynecological Service of the Johns Hopkins Hospital, Baltimore. Of the patients 90.3 per cent

reported that they were well, 5 per cent that they were benefited, 3.5 per cent that they were not benefited, and there was no data on 1.2 per cent.

There is more than one etiologic factor in stress incontinence. The explanation for the incontinence in the cases associated with urethrocele or cystourethrocele lies in the sagging of the urethra and base of the bladder. Defects in the pubovesicocervical fascia, which normally supports the urethra and blad-

Fig. 4. (Fe Linda.) Demonstrating use of Latako principle of partial colpocleisis for cure of vesicovaginal fistula in the presence of cured cervical cancer

der are responsible for both urethrocele and cystocele. The stress of coughing, sneezing, and other physical exertion forces the unsupported undersurface of the urethra and bladder downward, while the anterior surface remains in apposition to the symphysis. This prevents the urethral sphincter muscles from closing in a normal concentric manner and the resulting oval sphincter aperture fails to completely shut off the flow of urine (Fig. 1). The women without cystourethrocele usually present themselves after middle age, and the only explanation which can be offered is a decrease in sphincter muscle tone which occurs with advancing years. Still other women who suffer from stress incontinence are found to have scar tissue in the periurethral region which prevents the camera shutterlike action of the sphincter muscle.

The author discusses the operative procedures for the cure of stress incontinence and notes that the procedures are the plication of the vesical sphincter musculature and reuniting of the pubovesicocervical fascia fibers beneath the urethra and base of the bladder. A description of the operation performed by Kelly is presented and the operation done by the author is described. If a cystocele is present, an incision is made through the anterior vaginal wall from the cervix to within a half centimeter of the urethral meatus. If there is no cystocele, the incision is carried only the length of the urethra and for about a centimeter beyond beneath the trigone. The vaginal mucosa is dissected laterally the fascia being stripped from it. This fascia is to be used for subsequent plication to form a floor on which the urethra and bladder base rest. If a cystocele is to be repaired, the usual advancement operation is done with plication of the pubovesicocervical fascia in the midline. A series of mattress sutures of medium silk are taken,

beginning about a centimeter beyond the vesical end of the urethra and extending to within a half centimeter of the meatus. When the incontinence is marked the internal sphincter region can be more tightly plicated by taking 2 or 3 mattress sutures at that point, each succeeding suture burying the preceding one.

Because of the cases that are unimproved after the operation by plication it is necessary to find another method to cure stress incontinence. After one or more unsuccessful plications, scar tissue may make further plication futile. Moreover, in the case in which the urethra and sphincter mechanism have been destroyed the reconstructed urethra has no contractile power and this must be supplied from some other source. In certain neurologic bladder with incontinence there is the possibility that a new sphincter mechanism can be supplied which will function sufficiently well to give the patient control. For these conditions, the author uses a modified Goebel-Stoeckel operation. This type of operation has been done 13 times in his clinic during the past 10 years, and has been successful in all but 2 cases. This failure was apparently due to a great excess of scar tissue resulting from the previous attempts at plication.

This type of operation is described in detail (Fig. 2). Contrary to the objections of some, there was no hemorrhage nor injury to the bladder in the operation. Care is taken in each case to secure the proper amount of tension on the strips of fascia to give the patient continence. This is tested by distending the bladder through a glass catheter and creating moderate repressurable pressure.

The history of vesicovaginal fistula is briefly reviewed. In the study of the causes of vesicovaginal fistula in 41 cases, it was found that vaginal delivery caused 8 cases and total abdominal hysterectomy was responsible for 15 cases. Of 41 patients operated on 37 were cured. A discussion of the principles that have contributed to the success of this series of difficult operations is presented. The advantage of having the tissue in the best possible condition before attempting closure is great. After the occurrence of a fistula 5 or 6 months should elapse before surgery is attempted. The approach to the operative field should be given considerable thought. The vaginal approach is the one most favored. Even a deep vagina can be made relatively shallow by episiotomy.

The Latako method of closure of high vesicovaginal fistulas is recommended because it is so well adapted to the ever increasing number of fistulas following total hysterectomy (Figs. 3 and 4). Although partial colpocleisis is undesirable, the inconvenience is nothing compared to that of the pre-existing incontinence. In no case has a vesicovaginal fistula been approached transvesically by the author. The technique for the closure of the fistula is presented. To test the bladder closure the author uses a weak solution of sterilized milk. If there is a very slight leakage, the drop of milk stands out very plainly against the bloody background. The milk does not stain the tissue as does the methylene blue solution.

Fig 5 Implantation of ureter into bladder. A. ureter has been dissected free and cut across. Opening has been made through broad ligament into bladder and end of catheter has been introduced into it. Mattress sutures have been placed in end of ureter passed into bladder and cut through wall of bladder. B. Mattress sutures have been tied and a fixation suture placed through bladder wall and muscular coat of ureter. C. Bladder wall incision is approximated with a mattress stitch. D. This mattress stitch has been tied, and implantation has been completed. E. Uterus and serosal surface of bladder are sutured together to relieve any tension that might develop at anastomosis.

The author notes that many a perfectly executed operative closure is ruined by improper postoperative care. The essential point in postoperative care is bladder drainage. Frequently double drainage is provided in the form of a therapeutic vesicovaginal fistula or suprapubic drainage in addition to the indwelling urethral catheter. The vaginal cystostomy closes spontaneously in a remarkably short time, after withdrawal of the catheter 2 weeks later. If the incision has not been made through scar tissue ninety per cent of the fistulas in this series were cured by the application of these principles. Among the most difficult cases of incontinence to cure surgically are those resulting from complete

destruction or congenital absence of the urethra, including the region of the internal sphincter. Occasionally this may occur as a result of childbirth injury. The operation for restoration used by the author is briefly described.

Incontinence of urine due to ureterovaginal fistula usually results from operative injury to the ureter. While in some cases of injury urine may appear in the vagina almost immediately following the operation, more often the lower ureter sloughs as a result of accidental crushing or interference with its blood supply. Then urine appears in the vagina several days after the hysterectomy. To differentiate between a vesicovaginal and uterovaginal fistula the

INTERNATIONAL ABSTRACTS OF SURGERY

bladder may be filled with methylene blue solution. If the vaginal urine is unstained, it is the ureter which communicates with the vagina. It is desirable to allow as much as 6 weeks to elapse before undertaking the anastomosis of the segments of the ureter. If the operation is undertaken too soon, the pelvic tissues in the region of the ureter will be edematous. If one waits too long the function of the kidney will be reduced or even completely destroyed. The indications for and the types of implantation to be performed are presented and discussed. A discussion of the technique of a ureterovesical anastomosis is given (Fig. 5).

The author concludes by noting that from this review of the experiences of the past decade it is apparent that most cases of urinary incontinence are curable surgically. In order to effect a cure in a high percentage of cases, surgical principles which have evolved out of the experience of many operators during several decades must be heeded. Ingenuity in planning each case and meticulous care in executing the surgical procedures are essential but the reward is a successful outcome which transforms the life of the patient from an almost unbearable existence to that of a normal woman.

HERBERT F. TRUXTON, M.D.

On Pelvic Neurinomas in the Light of an Internet
Ing. Case. *Oldi Hietalaivara. An. chir. gyn. fenn.*
1947 36 7

An interesting case of pelvic neurinoma of the pelvis is described. This type of tumor was first described in 1908 by Verocay. While neurinomas have been described in other parts of the body their presence in the pelvis is uncommon, only 7 such cases having been reported. The case report becomes remarkable on account of the location of the tumor. Ganglioneuromas are the most common of the pelvic nerve tumors.

The tumor in the author's case was the size of a fist however the great majority of the neurinomas remain relatively small. Cesarean section was performed because of obstruction of the true pelvis.

Later the tumor was removed surgically because of symptoms of pressure. It was found to be retroperitoneal, solitary and originating from the anterior surface of the os sacrum.

Diagnosis is usually difficult. The only possible treatment is the surgical removal of the tumor. Radiotherapy has no effect. The prognosis is good.

T. FLORE BELL, M.D.

Clinical Study of Hydatid Mole (Clínica de la mola hidatídica) J. M. Bedoya. *Rev. esp. obst. ginec.* 1947 4 1

There are 3 types of moles to consider: the bloody mole which is merely a coagulated mass of blood more or less organized; the teratologic type which may or may not contain a fetus or some part of one; and finally the hydatid or hydatidiform mole. The last is characterized by the formation of a large number of vesicles hanging on a pedicle appearing much like a cluster of grapes. It is known by several terms such as vesicle mole, gestation mole, uterine hydatid, choriomyxoma, and degenerative cyst of the chorion villous.

The affection is a serious one as it often occasions the death of the fetus, endangers the mother and requires urgent intervention, much as malignant trophoblasts of the trophoblast and chorionepithelioma types.

According to the author the frequency of occurrence varies from 0.05 to 3.70 per 1000 and the condition is seen more often in multiparous women. The symptoms usually found are amenorrhea, expulsion of the vesicles, hemorrhage, pain, vomiting and other subjective signs of pregnancy and enlarged uterus or varian tumor. It is impossible to demonstrate a fetus. The mole may be expelled spontaneously or retained, or it may instigate a serious pelvic infection.

Treatment consequently resolves into one of expectancy or interference. The condition is treated either by hysterectomy or evacuation of the uterus medically by oxytocics or surgical interference.

STEPHEN A. ZIEGLER, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

The Etiology of Primary Abdominal Pregnancy (Per la genesi della gravidanza addominale primitiva)
Luigi De Giorgi Arch. ostet. ginec., 1947 52 1

Six normal deliveries in a 41 year old pluripara were followed by a placenta previa centralis for which a cesarean section on the uterine fundus was done. In the present pregnancy which was near term there were pains in the lower abdomen great tenderness to palpation and attacks of slight bleeding from the vagina. No evidence could be elicited that the fetus was alive. The subsequent symptoms of severe acute anemia indicated a laparotomy during the operation a massive hemoperitoneum and a large fibrin covered saclike formation containing a dead fetus was encountered. The child weighed 3,000 gm. and was 49 cm. in length. Subtotal hysterectomy with removal of both tubes and ovaries followed. The tubes and ovaries were apparently normal. The sac and placenta were attached to the fundus of the uterus the area of insertion involving the healed cesarean scar of the uterine fundus and extending to the left almost to the point of insertion of the left tube. The body of the uterus was enlarged measuring 11 cm. in height and 7.5 cm. in breadth. When it was opened the walls were found to be irregularly thickened and the cavity was lined with an membrane partially necrotic decidualeike

Histologically the muscular walls were intact forming a continuous layer of irregular thickness between the uterine cavity and the area of serosal implantation of the placenta and sac. Even surrounding the intramural portions of the tubes which areas were examined. In serial section the encompassing muscle tissue was intact. The serosal covering of the tubes and ovaries was smooth and continuous, the mucosal folds within the tubes were normal in appearance with evidence of decidual or regressive changes and there was no other evidence of primary attachment of the ovum in these structures. On examination of the area of placental attachment to the uterine fundus the chorionic villi were observed to extend down from a distance of about 2 cm. among the muscle fibers of the uterine wall, but were separated from the muscle tissue by wide lacunae filled with blood. The chorionic reaction had evidently produced some fibrosis and byaline degeneration in the muscle tissue but there was no clear evidence of decidual response. Nevertheless directly beneath the placental attachment and also scattered irregularly in the muscle tissue were some glandlike cavities lined by a necrotic desquamating epithelium. The muscular uterine wall particularly in the area of scar left from the previous hysterotomy, was noticeably thinned. The endometrium showed in addition to the necrotic changes observed macroscopically ad-

vanced decidual changes. The histologic findings in the placenta itself were about those of an ordinary placenta at term. The wall of the fetus containing sac was covered on the outside by layers of fibrin type and was lined by a single layer of low epithelial cells which were rich in protoplasm. The fresh status of the organs and other tissues of the dead fetus indicated that it had died recently.

The author believes that the case would be most logically considered an instance of primary abdominal pregnancy. It is regretted that the pregnancy had advanced so far that no conclusion could be formed as to the original conditions present in the area of nidation of the ovum. However the evidence of defective healing of the original hysterotomy scar (glandlike cavities) would suggest that an ectopic endometriosis may have spread as far as the serosal surface of the uterine fundus in the area of oval implantation. It is true that the conditions observed do not fulfill all the postulates of Veit however it is concluded that in view of the knowledge accumulated since 1903 these postulates are no longer tenable in their strictest sense.

JOHN W. BRIDGMAN M.D.

The Management of Ovarian Tumors Complicating Pregnancy Henry C. Paik and Irving A. Bunkin. Am J Obst 1947 54 82

Ovarian tumors are tumors of the childbearing period and they may thus complicate a pregnancy. The presence of an ovarian tumor therefore is as a rule no barrier to conception. Twelve cases of ovarian cysts complicating pregnancy are reported. In general, all the criteria which influence the handling of ovarian tumors in the nonpregnant patient apply equally as well to the pregnant patient.

Dermoid cysts are found to be a common complication of pregnancy. Dermoid cysts were present in 7 of the 12 cases, and in 2 of these the condition was bilateral.

The small ovarian cyst (5 cm.) is usually one of a group of functional cysts and it is rarely a cause for concern before or during pregnancy. Larger cysts should be removed when they are discovered in the nonpregnant patient. All lesions suspected of being solid tumors of the ovary should promptly be surgically inspected. Bilateral tumors also must promptly be submitted to surgery.

The medium sized and larger tumors discovered at the onset of gestation may be removed safely during the first trimester of pregnancy under general anesthesia, preferably cyclopropane. Instances of removal of both ovaries during the second and third month with no interruption of the coexisting pregnancy have been reported. Torsion intracystic hemorrhage and infection are the commonest complications during pregnancy. Torsion and infection occur most frequently during the postpartum period.

Ovarian tumors discovered during the second trimester of pregnancy should be removed at that time. In the elderly primipara it may be advantageous to delay oophorectomy until term at which time cesarean section may be done.

In patients in whom the ovarian cyst is discovered at term and delivery of the fetus through the natural passages is imminent, the ovarian cyst should be removed soon after delivery in view of the potential danger of torsion and infection. The cyst which makes for a dystocia problem at term should be removed at the time of the elective cesarean section.

JOHN R. WOLFE, M.D.

LABOR AND ITS COMPLICATIONS

Manual Removal of the Placenta. A Report of 418 Cases of Manual Removal of the Placenta with 1 Death; 150 of the Removals were Done as a Routine or Prophylactic Measure Harry W. Mayne, *West. J. Surg.* 1947 55 453

Four hundred and ten cases of manual removal of the placenta are reported from the Methodist Hospital in Brooklyn. One hundred and fifty of these were taken from 234 personal obstetrical cases of the author observed over a 10 month period. Only 1 death occurred, and there was a morbidity of 7.6 per cent. No deaths occurred among the 150 personal cases of the author and the corrected morbidity of this group was 0.66 per cent.

Vaginal antiseptics was used routinely and may have been a factor in the low morbidity. The technique of this vaginal antiseptics was as follows:

On admission to the hospital the perineum was sprayed with a 2 per cent solution of mercurochrome and the vagina was irrigated with 3 drams of the same solution. This was repeated every 12 hours until the patient was ready for delivery. At this time the perineum was cleaned with soap and water and sprayed with a 2 per cent acetone alcohol solution of mercurochrome. The perineum was then depressed and 3 drams of a 2 per cent solution of mercurochrome in glycerine were poured into the vagina. When manual removal of the placenta was anticipated the latter procedure was repeated three times.

Early manual removal of the placenta is indicated in the presence of an anticipated difficult third stage. The following conditions predispose the patient to a difficult third stage: polyhydramnios, twin pregnancy, a large baby, adherent placenta (placenta accreta), long labor, difficult delivery, version, or placenta previa.

The author believes that the hazard of infection can be overcome by routine vaginal antiseptics during labor and at delivery and that the blood loss, shock or trauma which may occur with the Crede maneuver or in the 1 or 2 hours delay following delivery may be prevented. Sulfu drugs and penicillin should be used if vaginal antiseptics is not provided, otherwise they are not necessary. There was very little blood loss in this group of patients. No patient was given a transfusion during her stay in the hospital.

Although manual removal of the placenta immediately following delivery is an apparently harmless procedure when vaginal antiseptics are used during labor and at delivery it is not recommended as a routine procedure.

HARRY FIELDS, M.D.

NEWBORN

Icterus Neonatorum; Its Incidence and Cause Leonard Findlay, George Higgins, and Margaret W. Stanley, *Arch. Dis. Child.*, Lond., 1947 22 65.

Icterus neonatorum occurs in anywhere from 10 to 80 per cent of the newborn, according to the various estimates. Since the detection of jaundice is influenced by many factors such as the vascularity of the skin and the nature of the light in which the observation is made, and since there are several definitions of jaundice, such varying estimates are not surprising.

The authors' study is based on an investigation of children born in the Maternity Department of the Radcliffe Infirmary, Oxford, and was undertaken with the idea of (1) determining the incidence of icterus neonatorum, (2) trying to detect any difference in the rate of hemolysis in jaundiced and nonjaundiced infants, and (3) discovering any evidence of impairment or immaturity of liver function.

The diagnosis of icterus neonatorum was made on the basis of a hyperbilirubinemia in the cord blood or postnatal blood of an otherwise normal infant. Hyperbilirubinemia is defined as a plasma bilirubin level greater than 1 milligram per cent. This arbitrary level is chosen as it is unusual to find in a normal adult a plasma bilirubin level above this figure.

Seventy-three infants were observed once during the first 10 days of life and of these 34 infants (46%) had plasma bilirubin levels between 1.5 and 20.0 milligrams per cent at the time of the examination. Eighteen infants with levels above 2 milligrams per cent showed jaundice. All infants with bilirubin levels above 5.0 milligrams per cent showed icteric discoloration of the skin and mucous membranes. The higher the level of fetal bilirubin the greater is the chance of the development of jaundice.

No correlation exists between cord plasma bilirubin concentration and the maturity of the fetus. There is also no absolute correlation between the fetal level and the postnatal rise of the plasma bilirubin. Hyperbilirubinemia was present at some stage during the first 10 days of life in 81 per cent of the cases. Premature infants are more likely to develop jaundice than the mature ones. All infants born before 35 weeks developed jaundice, 67 per cent born after 36 weeks developed jaundice, and only 47 per cent of term infants developed jaundice. These figures refer to actual jaundice and not just hyperbilirubinemia.

Several factors have been suggested in the past as possible causes of icterus neonatorum. Excessive hemolysis or hepatic immaturity or both, have been most frequently mentioned.

Evidence is presented to indicate that red-cell destruction and bilirubin formation take place in the newborn at a rate no greater and perhaps lower than in adults. It, therefore, seems probable that the hyperbilirubinemia is due to the failure of the liver of the newborn child to excrete the pigment at the normal adult rate. It is only after birth that the liver starts to take on many of its functions.

There is reason to think that at birth the route of bilirubin excretion changes suddenly from the placenta to the child's own liver and if the child's liver were functionally immature at birth a temporary accumulation of bilirubin in the blood could readily be explained.

The authors have investigated the state of hepatic function by a study of the plasma protein and Takata Ara reaction during the first 10 days of life and of the excretion of fecal bilirubin during the first 5 days of life. There is no correlation between the changes in the plasma protein, as measured by the Takata Ara reaction and the degree of hyperbilirubinemia. It is evident that the changes in the plasma protein do not reflect the ability of the liver to excrete bilirubin.

Fecal bilirubin studies revealed a tendency to earlier and greater excretion in the nonjaundiced infants, with the lowest and slowest excretion in the severely jaundiced infants.

The authors conclude that their studies support the view that icterus neonatorum is due to hepatic immaturity.

HARRY FIELDS, M.D.

On the Prophylaxis of Hemolytic Disease of the Newborn. Donald H. Karlier and Dorothy I. Miller. *Am J Obst.*, 1947 54: 1

Hemolytic disease of the newborn may be diagnosed in the as yet unborn infant by routinely testing the sera of all Rh negative mothers during their pregnancies for the presence of one or more of the Rh antibodies and obtaining titers of the amount of antibody if any is present. Being aware before delivery of the fact that an infant with hemolytic disease of the newborn is to be delivered, one can make preparations for the proper treatment of the infant following its birth. This preparation and treatment resolves itself into having available Rh negative blood of the proper group and giving the infant a transfusion immediately at birth or as soon thereafter as seems justified by its condition and, particularly, by the red blood cell and hemoglobin levels. Repeated blood transfusions are nearly always necessary. Although this form of treatment has been helpful and has reduced the mortality from this disease, it is far from satisfactory.

The ideal treatment which would actually be prophylactic in nature is the treatment of the mother during her pregnancy. This treatment could be directed at one of three objectives: (1) the prevention by some chemical means of the antigen-antibody reaction from going to completion; (2) the absorption of the antibody as soon as it is formed by means of Rh haptene injections; or (3) inhibition of antibodies

by some immunologic means. The authors attempted the third method by giving a patient weekly injections of typhoid vaccine with the thought that a stronger antigen would prevent the weaker Rh antibody formation, but she was delivered of an infant which died from hemolytic disease of the newborn on its fourth day of life. Rh haptene has not been obtained in any form which would make it useful clinically.

The authors present 3 cases of patients who have been treated with the first objective, the prevention by some chemical means of the antigen-antibody reaction going on to completion. In 2 patients the condition was due to an Rh incompatibility in 1 to O-A incompatibility. All 3 patients had been previously delivered of one or more infants who died of hemolytic disease of the newborn as proved by autopsy and study of the placenta.

Since the production of this disease is essentially an antigen-antibody reaction, the idea suggests itself that if one portion of the reaction is eliminated, the reaction cannot go on to completion. Since the antigen is the fetal red cells, some process of preventing the production of antibody formation or of destroying it as rapidly as it is being produced must be achieved. Since the disease is produced by the continued action of the antibody in the maternal serum on the fetal cell antigen, the elimination of all antibody from the maternal serum would prevent the hemolytic disease.

With this fact in mind the authors used a drug ethylene disulfate 1:10-15 dilution in triple distilled water. Since the amount of the drug injected (2 c.c. of the 1:10-15 dilution) is so infinitesimal the authors believe that the results are due to the tissue damage produced by the distilled water and the liberation of an "x" substance which when picked up by the blood stream will neutralize all the circulating antibody. The 3 patients were given 2 c.c. of the drug in weekly intramuscular injections during the last 3, 4, and 6 months, respectively.

By following the therapy described 2 patients were delivered of infants who were normal and healthy both at birth and on subsequent examination. Although the third patient was delivered of a baby with hemolytic disease, the previous pregnancies had resulted in a stillbirth due to hydrops fetalis and an abortion. This infant was alive and responded to transfusion.

The method is presented with the hope that others will corroborate the findings, and not as a cure for hemolytic disease of the newborn.

MISCELLANEOUS

Uterine Accommodation of the Products of Conception; Physiologic Considerations. S. R. M. Reynolds. *Am J Obst.*, 1947 53: 901

The size and shape of the gravid uterus is a necessary and primary subject of interest to the obstetrician. When it is given consideration it is usually with

respect to the morphology of the uterus or to the size of the conceptus with respect to the estimated age of the pregnancy. More recent studies made on infirmities suggest that still other attributes of uterine accommodation of the products of conception will bear the attention of clinician and experimenter alike, for these pertain to important physiologic mechanisms that are concerned with fetal growth and welfare. The new data have already yielded conclusions which promise to provide a common basis upon which certain of the functional and seemingly unrelated, difficulties of late pregnancy may be explained. Uterine accommodation of the products of conception appears to be the common physiologic denominator to these situations.

The local circulation of the maternal blood in the uterus decreases gradually as the fetus increases in size. Suddenly as the fetus reaches maximum ovoid size a profound transitory decrease in uterine circulation (uterine ischemia) takes place. The fetus changes shape abruptly by elongation and with this, there is restoration of a rapid circulation of the maternal blood through the uterus. The existence of an ovoid shape with respect to the conceptus even though intrauterine pressure is low imparts a relatively high degree of tension about the conceptus.

In pregnancy hypertrophy of the uterine tissues is associated with uterine distention by an ovoid conceptus. Consequently it takes place at the time of maximum uterine tension. After elongation of the products of conception, uterine growth decreases sharply and at this time there is the least possible increment in uterine tension with fetal growth. The last trimester of pregnancy (when fetal growth is most rapid) consists of "paying out" tissue elements which increase first by hyperplasia and then undergo hypertrophy in earlier periods of pregnancy.

Since transitory uterine ischemia is a necessary concomitant of conversion of the conceptus from an ovoid to a cylindrical shape, the possible consequences of abnormal manifestations of this on the welfare of the maternal organism, of the fetus, or both, is suggested. The essential application of this discussion to practical obstetrics is that it emphasizes the physiologic basis of proper change in shape of the uterus for normal pregnancy particularly about the beginning of the last trimester of pregnancy.

Uterine ischemia of given degree or duration may bring harm to the maternal organism by giving rise to toxic manifestations, or it may give rise to local conditions which jeopardize the continuance of the pregnancy or the viability of the fetus.

JOHN R. WOURT M.D.

Lymphogranuloma Venereum in Obstetrics.
Charles M. Steer *Am J Obst* 1947 54 230.

Lymphogranuloma venereum is a virus disease which produces a small primary lesion and systemic manifestations in its early stages, and localizes later in the genitalia and lower bowel. It is a rare disease in general and even more rare in association with pregnancy.

At the Presbyterian Hospital in New York, New York the diagnosis of this disease was made in 14 cases during a period of 15 years (an incidence of 0.045 per cent). On the obstetrical service (Sloan Hospital for Women), there were 8 cases among 22,500 admissions in the same period (an incidence of 0.036 per cent). Seventy five of these occurred in women of whom only 7 were white.

There were 45 patients in this group who became pregnant before the disease developed. The remaining 30 never became pregnant. No patient conceived for the first time after the disease appeared. Thus, this disease leads to an impairment of fertility.

When conception occurs in a patient with rectal or genital involvement there may result a normal pregnancy and a spontaneous delivery but in other cases (and it is impossible to predict which ones these will be) there may be a flare-up of the disease during the pregnancy or the rectal involvement may proceed to the point of complete intestinal obstruction. Because of these possibilities, it would seem wise to advise against pregnancy in a patient with active disease or with a rectal stricture. Termination should be considered if pregnancy has occurred in such a patient. The chief danger which exists at the time of delivery is that of rupture of the rectum. In the reported cases this has always resulted in death and this accident has been associated with an operative procedure in all but 1 case. This means that vaginal delivery of a patient with rectal stricture exposes her to the possibility of irreparable damage.

It is true that a number of patients with complications have been delivered from below and this number is greater than the number of those who have died. But with so great a risk, it would seem wiser to deliver all patients with rectal strictures or the genital syndrome by cesarean section. When that cannot be done the delivery may be allowed to take place normally if operative interference is kept to a minimum, and, when interference cannot be avoided, the manipulations should be as gentle as possible.

JOHN R. WOURT M.D.

Analysis of Therapeutic Abortions at the Bellevue Hospital, 1935 to 1945. Irving K. Perlmutter
Am J Obst 1947 55 1008.

While the occasional necessity for the interruption of a pregnancy, to preserve the life of a mother has been recognized since ancient times, the difficulty of defining the borderline between such therapeutic procedures and criminal abortions has always existed. Neither the legal nor the medical profession has helped to clarify the issue, since the former has failed to provide a clear statement of society's attitude, while the medical profession has failed to define the conditions which call for a therapeutic abortion.

An analysis of the therapeutic abortions performed at Bellevue Hospital, New York, from June 1, 1935 to May 31, 1945 was undertaken in order to re-evaluate the policy for that institution. It was found that 199 pregnancies were interrupted on the gynecologic

service while during the same period 15 119 women were delivered on the obstetric service. The incidence of therapeutic abortion was therefore 1.23 per cent, or a ratio of 1 therapeutic abortion for every 76 women delivered.

The indications for therapeutic abortion have been under constant revision since this procedure was first introduced. The earliest indication noted in the literature of the eighteenth century was for contracted pelvis. In the middle of the following century a gradually increasing scope was evolved which embraced indications for cardiac disease, tuberculosis and many neurologic and psychiatric disorders. The use of therapeutic abortion continued to broaden until the turn of the century when the first evidence of conservatism became apparent and the medical profession took a more critical view of the indications. That this trend continues is indicated by the present analysis.

The survey is divided into two 5 year periods with a ratio of one abortion to every 64.6 women delivered in the first 5 years, and a ratio of one abortion to every 93 women delivered in the second 5 years. The relative trends within groups show an apparent increase in tuberculosis (47.89%) an apparent unchanged incidence in the cardiac and toxemia-pyrexia indications, and an apparent decrease in neurologic and psychiatric indications. The large groups containing all the remaining miscellaneous indications for therapeutic abortion also show a declining incidence. Several can be removed from the present day indications by recent advances in medical management.

A comparison of the number of therapeutic abortions performed with the number of deliveries of

women with the same medical complication showed that the indications for all therapeutic abortions are on the decrease, whereas the number of deliveries of women with the same medical complication is on the increase.

Management of Postabortal Peritonitis. Henry C. Falk and George Blalock. *Am J Obst* 1947 54 314.

An analysis of 61 fatal cases of postabortal peritonitis not associated with perforation of the uterus seen at the Harlem Hospital New York New York, showed the inadequacy of conservative therapy. Not 1 patient who was proved to have postabortal generalized peritonitis recovered. Because of this knowledge and the similar experiences of others the entire problem has been restudied and since 1941 selected cases of postabortal peritonitis have been treated with surgery.

Since 1943 24 cases of generalized postabortal peritonitis have been seen at Harlem Hospital. Thirteen patients were not operated upon and all of these died.

Surgery was performed on 11 patients and 8 of these have survived. The surgical procedure consisted of hysterectomy with splitting of the cervix and vaginal drainage. This was combined with appropriate chemotherapy. Multiple blood transfusions and intestinal drainage. For technical reasons and to decrease shock, supracervical hysterectomy with splitting of the posterior lip of the cervix and the insertion of multiple drains into the pelvis is preferred to total hysterectomy. Vein ligation was not employed and is not deemed an essential adjunct to surgery.

JOHN R. WOLFF M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Tumors of the Kidney A. P. Graham. *J Urol* Balt., 1947 58 10.

Initial symptoms in 70 per cent of 195 patients with malignant tumor of the kidney were hematuria and pain 31 per cent, or about one-third of these patients, complained of hematuria only.

The finding of a palpable mass in 41 per cent of the patients at initial examination indicated that the diagnosis of cancer of the kidney was made very late.

Retrograde pyelography was diagnostic in 66 per cent of the pyelograms taken. Compression of one or more calyces (59 per cent) and distortion or compression of the pelvis (22 per cent) comprised 81 per cent of the significant pyelographic findings.

Intravenous pyelography was diagnostic in only 16 per cent of the pyelograms compared with 66 per cent for the retrograde.

Eighty-six per cent of the tumors were considered to arise in the parenchymal portion and 14 per cent were pelvic or calyceal in origin. The squamous tumors did not metastasize widely whereas the transitional cell neoplasm produced extensive metastases to many organs and structures. Sixty per cent of the transitional cell tumors had become implanted in the ureter or bladder during the period of observation or previously.

Metastases were found in 70 patients or 36 per cent, at the time of initial examination. Forty-eight per cent of these were in the lungs, 23 per cent were bone metastases, 9 per cent were in the liver, 7 per cent were proved brain metastases, hence 7 per cent of the metastases were in the lungs or bone.

Bone metastases were most prevalent in the ribs, ribs, and pelvis.

Finding 41 per cent of the tumors inoperable when first seen would indicate that not much has been accomplished toward early diagnosis of cancer of the kidney. At least in the group of cases with which we are dealing. And further in 21 metastases found at time of surgery 8 were found inoperable because of local extension.

There were 28 per cent 3 year cures, 17 per cent 5 year cures, and 14 per cent 10 year cures.

JOHN A. LOSE, M.D.

Biological Assay of Kidney Tumors by Heterologous Ocular Transplantations. M. H. Blaska. *J Urol* Balt., 1947 58 1.

The tumors of the kidney utilized in this investigation comprised (a) 1 papilliferous epithelioma of the renal pelvis from a white man aged 37 years, (b) clear cell carcinoma from a white woman aged 61 years and (c) 1 granular cell carcinoma from a white man aged 60 years.

In this group a total of 9 transplantations were effected with 1 positive histological result, while in 3

instances the histological evidence was equivocal and in another 3 it was definitely negative. Transplant was completely absorbed, and in the last case the result was indeterminate.

In the positive result, the transplant was surrounded by a fine network and a pseudocapsule due to a desmoplastic reaction originating in the host (guinea pig). In this positive transplant, the morphological characteristics of the original tumor were maintained without aberrant changes in the cells or nuclei.

There were 3 clinically positive results, the transplants increasing in size with alterations in color and vascularization but the histology of the transplant did not reveal any definite evidence which would suggest viability of the transplant when examined on the sixteenth, twenty sixth and thirty third post-transplantation days. Histocytes were predominant in these transplants, together with leucocytic infiltration. Again, in the 3 transplants with equivocal results it was not possible to reach a definite conclusion because the cells which questionably simulated granular cell carcinoma did not display irregularity in their size, shape and staining reaction, and in the staining reaction of the nuclei, features which are suggestive of malignant proliferation.

JOHN A. LOSE, M.D.

BLADDER, URETHRA, AND PENIS

Treatment of the Paraplegic. G. J. Thompson, M. N. Nourse, and H. C. Bumpus, Jr. *J Urol* Balt. 1947 57 685.

Teamwork between the various departments involved in caring for the paraplegic is essential to maximum recovery. In the past the principal cause of fatality has been infection of the urinary tract, therefore restoration of function of the bladder and prevention of deterioration of the kidneys are of primary importance and the urologist should direct the early treatment.

The authors present their observations of 101 patients suffering from injury or disease of the spinal cord. The majority of patients were below 40 years of age and the condition in most cases was caused by gunshot wounds or traumatic fracture. In 46 cases the lesion was above the tenth vertebra and in 55 cases at the eleventh thoracic vertebra, or below.

In a general discussion of the cases, hemithorax is mentioned as being the most debilitating complication and the most important single therapeutic agent was found to be a palatable high protein diet provided by 4 meals daily.

The type of drainage varied. In 19 cases a suprapubic cystostomy was done and in 81 cases drainage was through urethral catheters (No. 18 Foley bag being most satisfactory). Tidal drainage was used in the majority of cases but not exclusively or con-

unusually. It was found that irrigation with a pistool syringe kept the bladders cleaner than did tidal irrigation alone.

Stones were observed to form in the bladder to 67 patients in 11 cases stones formed in one kidney and in 8 cases both kidneys were involved. Early mobilization and adequate hydration were found to be the best preventatives of stones.

In this group transurethral resection of the vesical neck was done in 58 cases, in some instances 2 or 3 resections were required. The authors observed that most patients manifest one of two types of neurogenic dysfunction: (1) the so-called automatic or reflex type of bladder or (2) the so-called retention type, with overflow incontinence. The reflex bladder was established most speedily in cases in which the injury was above the tenth thoracic vertebra and which the injury was below the eleventh thoracic vertebra. The authors believe that in the latter group with lesions of the cauda equina the bladder becomes an overflow bladder with varying amounts of residual urine present at all times and that it is these cases which are most responsive to resection.

Cystoscopic examination shows various degrees of relaxation of the neck of the bladder—some cases present a constriction of the internal urethral orifice, some have a bar type deformity and others may have a vocal cord appearance. All cases show trabeculation of the wall of the bladder and this is interpreted as a work hypertrophy caused by efforts of the bladder to empty. Relief of the obstructive element by resection will enable these patients to empty their bladders by straining their abdominal muscles.

The authors believe that it is safer to perform several operations than to attempt too wide a resection initially. The other condition in which transurethral resection is indicated is that in which a reflex bladder has been established but fails to empty well. Reoperation often results in a more efficient emptying.

Of 39 patients with injury below the eleventh vertebra and who had undergone transurethral resection, 36 had voluntary urination. An analysis of 43 cases in which resection was not necessary or not indicated disclosed that 13 patients had voluntary urination and 30 had efficient reflex type emptying. In this series satisfactory bladder function was established in 93 cases in 40 cases this was voluntary and in 53 automatic. The urine in 85 patients was grossly clear, and in 39 patients the urine was negative culturally. After the patient has dispensed with the use of a catheter and is free of stones there is a chance to sterilize the urine.

ROBERT G. BEADLES, M.D.

Utilization of X Rays in Tubercular Cystitis as a Preparation for Endoscopic Examination. Clin. Contrib. Tuberculari a scopo preparatorio alla esame endoscopico Contributo clinico. Eros Benedetti Ann. chir., 1947 24 128.

Three patients with tuberculous involvement of a kidney and a secondary tuberculous cystitis com-

licated in each instance by a banal pyogenic infection were given from 360 to 400 roentgens previous to an attempt at cystoscopy. In each instance the bladder was edematous congested, infiltrated and enormously contracted holding only from 10 to 30 c.c. One of the patients had been discharged from a surgical clinic in another city with the statement that cystoscopy was impossible. The irradiation was given from in front with protection of the genitalia. Each patient was given from 80 to 100 roentgens in each of 4 sessions at 2 day intervals. A penetrating ray (180 kw) was used and superficial caustic effects were guarded against by filters of 34 mm. of copper and 3 mm. of aluminum. The focal skin distance was 40 cm. With the first sessions the condition in the bladder would seem to become worse with greater tenesmus and a more turbid even sanguinopurulent urine. Within a few days however these manifestations would begin to clear up and within 2 or 3 weeks the bladder had become sufficiently relaxed to permit of satisfactory endoscopic exploration with a 100 to 130 c.c. capacity. One of the patients refused the nephrectomy operation and did not come back however the other 2 had their tuberculous kidneys removed and have remained perfectly well 3/4 and 1 year respectively.

Irradiation is not considered to attack either the tuberculous organism or the secondary invaders (staphylococcus streptococcus). The author thinks that this form of treatment exerts an effect on the congestion edema and infiltration produced principally by the pyogenic secondary invaders and perhaps some additional influence on the process of phagocytosis and the reticuloendothelial system in general. The method is harmless and requires much less time than the usual lavages, rest in bed and oral medications even should they be successful.

JOHN W. BRENNAN, M.D.

GENITAL ORGANS

Testicular Biopsy in the Sterile Male. Fred A. Simons and Ronald Sniffen. *Brit J Surg* 1947 55 503.

Since 1940 over 300 biopsies of the human testicles have been secured surgically by the author (Simons) and studied in conjunction with Ronald Sniffen Associate Pathologist. The cases include all types of endocrine abnormality in patients from 16 months of age to 73 years. From this group were selected 85 patients whose chief complaint was sterility. Testicular biopsy whose chief complaint was sterility only after the wives of these patients had been found normal. Sixty five wives were studied personally by the author and 16 of these achieved pregnancy following testicular biopsy. An attempt at epididymotomy or semididymotomy (artificial insemination from an unknown donor). Approximately 50 percent of the patients were operated upon as office patients. The procedure is innocuous, safe adequate and diagnostic. Pentothal and spinal anesthesia also were used.

The test is valuable as a means of deciding whether repeated azoospermia is due to block or germ plasma failure or in differentiation of patients who may and those who may not respond to treatment. There is little correlation between the microscopic findings and the findings at physical examination or between the urinary hormone assays and semen study except that all patients with too much follicle-stimulating hormone had malfunctioning tubular epithelium. By means of histological investigation the cases were thus classified and better understood.

HARRY W. FICK, M.D.

Study of the Vascularization of Autoplastic Transplantations of Testicular Tissue in Various Locations (Ricerche sulla vascolarizzazione degli innesti autoplastici di testicolo fatti in varia sede) Gaetano Bianchi and Guido Galeotti. *Spermatologia*, 1947 95 294.

Autotransplants of tissue blocks from the testicle of the rabbit were inserted into the animal's own testicle on the other side into a pocket of its peritoneum, and into its adductor muscles of the thigh. After periods of from 1 to 35 days the animals were sacrificed and the abdominal aorta was immediately injected with colored gelatin according to the method of Fassari. The object was to see if the blood vessels growing in from the implant bed of the host tissue would reunite with the vessels already present in the implant or if the revascularization would consist entirely of new formed vessels, the vascular network already present in the implant being disregarded.

It was found that the newly formed vessels from the bed did unite with the original vascular network of the implant, however the circulation was not returned to its original state. This renewed circulation was most extensive in the tissue taken from the animal's testicle and implanted into the testicle on the other side. It was not so satisfactory in the implantation into the omentum, and was almost nil in the implantation into the muscular tissues. However if observed long enough all the implants in this series, no matter what their place of implantation, eventually lost this original blood supply were invaded by newly formed vessels, and were absorbed and replaced by fibrous scar tissue.

The difference in response in the 3 locations forces the authors to conclude that an individual homogeneity exists, not only between the so-called nobler tissues, or parenchyma, but also as postulated by Fassari, between their supporting tissue, or stroma.

JOHN W. BROWN, M.D.

Gangrene of the Scrotum. R. G. Robinson. *Gry's Hosp. R. & Lond.*, 946 95 92.

The author reports 3 cases of gangrene of the scrotum, gives a cursory review of the literature and discusses the pathology and treatment of this uncommon condition.

The disease was first adequately described in 1834 but the etiological factors were not well understood

until Meleney in 1933 classified infectious gangrene of the skin into acute and chronic forms. The acute type consists of 2 varieties—gas gangrene and hemolytic streptococcal gangrene.

The latter gangrenous infection may follow a deep wound but more frequently follows a trivial injury. There occurs a sudden onset of pain to the involved part with swelling of the site of injury which becomes hot and red. The pain gradually leaves but the area of redness spreads rapidly during the first 3 days. The marginal edges are not raised. The temperature is between 101 and 102 F with severe prostration. A small gangrenous patch appears between the second and fifth days with rapid spreading of the necrotic area. Distant subcutaneous tissue may become involved and many of the patients succumb to an overwhelming toxemia with septicemia. Hemolytic streptococci are always found associated with wound contaminants. The subcutaneous tissue is involved and thrombosis of the skin arteries results in secondary gangrene of the overlying skin. The disease has been reproduced in rabbits by injecting hemolytic streptococci subcutaneously.

The author states that infectious gangrene due to hemolytic streptococci and gangrene of the scrotum are one and the same disease. Cases reported by others due to associated organisms are probably sub-varieties of the disease. The author considers gangrene of the scrotum as a variety of hemolytic streptococcal gangrene that may affect any part of the body.

Surgical treatment of gangrene of the scrotum is fraught with a high mortality. The author believes that this disease is due to the hemolytic streptococci and should be treated with penicillin therapy alone.

PETER L. SCARFINO, M.D.

Studies on Intraocular Implantation. B. Krichsky and J. A. Benjamin. *J. Urol. Balt.*, 1947 58 114.

The administration of estrogens in doses up to 500 immunizing units per kgm. to intact animals produces a marked atrophy of intraocular prostate gland implants. This atrophy is reversible if the administration of estrogen is stopped.

After atrophy due to castration had manifested itself similar treatment of these animals produced marked hypertrophy of the intraocular prostate gland implants.

The atrophy in intact animals is due to glandular involution, while the hypertrophy observed in castrated animals is due to thickening of the fibrous and muscle tissue, and to hyperplasia and metaplasia of the epithelium.

It is suggested from this study that changes in the size of the intraocular prostatic gland implants in intact animals treated with natural and synthetic estrogens is the result of two processes: (1) atrophy due to glandular involution, and (2) hypertrophy due to fibromuscular changes and metaplasia of the epithelium. Usually the overall effect on the size of the prostatic tissue is reduction in the area of the transplant.

Intraocular prostate gland implants responded similarly to natural and to synthetic estrogens.
JOHN A. LOFF M.D.

MISCELLANEOUS

Urology in the European Theater: World War II
J. C. Kimbrough. *J. Urol.*, Balt., 1947 57 1105

The greater part of the urologic surgery of World War I was performed by the general surgeon urologist. Urologists were assigned to the task of venereal disease control and prevention. Between the two world wars, urology developed into a distinct surgical specialty. The urologists of World War II for the most part, were assigned to the surgical management of urological problems. The control and treatment of venereal disease was under the aegis of the Medical Service.

From June, 1942 until June, 1944 the urologic injuries were due to the activities of the army training program and to air combat. Automobile, jeep and motorcycle accidents accounted for the majority of injuries and these injuries presented no unusual problems to the civilian urologist. The greater part of this period was spent in preparation for the continental invasion.

From June, 1944 until May 1945 an efficient system of evacuation and treatment was set up on the continent. Urological treatment in the forward area consisted chiefly of the emergency management of wounds of the kidney and bladder and the conservation of tissue in injuries of the external genitalia. With victory on the continent, treatment was carried on without interruption of the patient physician relationship. In hospital centers, facilities for treatment were established in the various specialties.

From June to October 1944 147 bodies of men killed in aircraft combat were examined. Fourteen of these had injuries to the genitourinary system—9 had lacerations of the kidneys, 3 had ruptured or penetrated bladders and 3 received injuries to the external genitalia. Five of the 14 had received wounds resulting in fractures of the bony pelvis.

The mobile conflict on the continent accounted for an increase in the percentage of wounds due to high explosives. A cross-section review of 235 cases involved in 33 patients the kidneys were injured in 24, and the external genitalia in 160. There was a notable increase in the incidence of ureteral injuries which may have been due to better diagnostic measures. Conservative treatment of the renal injuries resulted in only 8 nephrectomies and 1 death. It was noted that ureteral injuries were frequently missed at primary operation because of the massive injuries sustained by these patients. When missed at the initial operation fistulas developed and nephrectomy was required. Early surgery in wounds of the ureter and bladder gave the best results. The repair of injuries to the external genitalia were performed as soon as practicable and tissue conservation was stressed.

Neurogenic bladders due to lesions of the brain and spinal cord were managed by (1) indwelling urethral catheters until the patient recovered, died or had a cystostomy (2) catheter drainage tidal or otherwise was maintained until bladder function returned, or it was determined that function would not return (3) suprapubic cystostomy at the end of 4 weeks or earlier if bladder function showed no evidence of return or if severe infection of the lower genitourinary tract developed.

Of the 193 patients with lesions of the nervous system, 130 had a cystostomy and 163 had catheter drainage, tidal or otherwise. Bladder function returned in 44 patients treated by urethral drainage in from 27 days to 56 days.

Attached to the article is an appendix copied from section A, chapter VIII, of the Manual of Therapy ETO May, 1944 which lists the methods of diagnosis and the treatment for wounds of the genitourinary system.

PETER L. SCARDINO M.D.

Urology in Naval Medical Corps, World War II
F. P. Twinnem. *J. Urol.* Balt., 1947 57 1129

An interesting account of the varied experiences of a senior United States Naval Medical Officer is reported by the author. It is based on 4 years of active duty in the United States and on Pacific Island bases. The duties of the medical officer were not limited strictly to the practice of his specialty or to the ordinary duties of medical personnel.

A comparison of the mortality figures of injuries to the genitourinary tract in World War I and World War II revealed a marked decrease in the recent war due to modern therapeutic methods in combating shock and infection and in the handling of casualties.

A tabulation of the case incidence and mortality resulting from traumatism, exclusive of combat casualties during the recent war in the United States Navy and Marine Corps personnel from 1942 through 1944 revealed a total of 38 cases of injuries of various types to the bladder with 3 deaths, 467 cases of injuries to the kidney (310 of which were due to contusions) with 1 death, 128 cases of injuries to the urethra with 1 death, and 7 cases of injuries to the ureter with no death.

Sustained dehydration, malnutrition, and debilitation resulted in a high incidence of urinary calculi which for the most part consisted of calcium oxalate and phosphatic calculi and were spontaneously eliminated or removed by cystoscopic procedures. It was noted that the incidence of urinary calculi was much higher in white personnel than in colored and almost nil among the Pacific Island natives.

Cord bladders were treated by tidal irrigation with an acid solution often combined with estrogenic and aluminum hydroxide gel therapy. When urinary calculi were composed of calcium phosphate or carbonate, magnesium phosphate, or triple phosphate these measures gave satisfactory results. Neurogenic bladders associated with vesical neck obstruction were treated by transurethral resection of the

obstructing tissue. Partial transection of the cord resulted in only 1 case of incontinence in a series of 40 cases reported by Prather. The author reports the promising results of the work of Hoen and Ney on the surgical treatment of cord bladder by anastomosing the twelfth thoracic and third sacral nerves.

The case incidence rate per 1,000 average strength of gonorrhea and syphilis during the 2 world wars revealed the average rate for gonorrhea during 1918 and 1919 was 55.40, whereas the average rate for the years 1942, 1943, and 1944 was 28.69. The average rate for syphilis for 1918 and 1919 was 14.55 whereas for 1942, 1943, and 1944 the average rate was 4.23. It was the author's impression that the venereal disease problem would increase immediately with the advent of peace after the recent war as it did after World War I.

Penicillin and sulfathiazole therapy combined cured 98 per cent of the cases of gonorrhea in a series of 1,100 cases at St. Albans Naval Hospital, St. Albans, New York. Satisfactory results were obtained in the treatment of syphilis with the following treatment schedules:

1. Primary seronegative 100,000 units of penicillin every 3 hours for a total dosage of 6,000,000 units.

2. Primary seropositive, secondary and latent 100,000 units of penicillin every 3 hours for a total dosage of 8,000,000 units.

3. First relapse or reinfection of previously treated syphilis cases 100,000 units of penicillin every 3 hours for a total dosage of 8,000,000 units. Concurrent intravenous injections of mapharsen (60 mgm.) twice weekly for 5 weeks for a total of 600 mgm., and intramuscular injections of bismuth subsalicylate in oil 1 1/2 c.c. (900 mgm.) each week for 5 weeks for a total dose of 1,000 mgm.

4. Second relapse of previously treated cases of syphilis 80 weeks of the mapharsen bismuth schedule.

Penicillin was used with satisfactory results in the treatment of yaws. The author observed the varied symptomatology associated with filariasis in the natives of the Pacific Islands. The Samoans were observed with advanced stages of the disease while the natives on Tarawa manifested few or no symptoms in spite of positive blood stream infection with microfilaria. The military personnel either did not contract the disease or when infected, showed only minimal symptoms. The microfilaria was never found in the blood of the military personnel. The disease runs a self limited course but requires active psychotherapy and rehabilitation because of the loss of libido and potentia. No permanent disabilities were noted among the military personnel who had the disease.

PETER L. SCARDINO, M.D.

War Wounds of the Genitourinary Tract O. S. Caalp. *J. Urol. Balt.*, 1947 57 7

The author reports his observations of 160 patients with injuries to the genitourinary tract who came under his supervision in the Communication Zone of

the European Theater of Operations during World War II. The causative agent in 67 per cent of the wounds was fragments from high explosive shells. Associated trauma to other systems influenced the treatment of the various urologic injuries. Fracture of the lower extremities or of the pelvis, or both, were the most frequent complications in the genitourinary injuries. Perforation of the intestines was the most frequent complication in all urethral injuries.

Fifty-four cases of wounds of the external genitalia without involvement of the urinary tract presented the same problems as soft tissue injuries in other parts of the body, except for the need of preserving as much penile and testicular tissue as possible. The residual infections were minimized by the generous use of antibiotics and sulfonamides. Repairs of nonabsorbable sutures gave the best results. Postoperative erections were satisfactorily controlled with diethylstilbestrol. The estrogens were discontinued after removal of the sutures with subsequent return of potentia.

The most common form of emergency treatment of the 86 patients with injuries to the urethra was suprapubic cystostomy. Twenty of the patients had defects in the anterior segment and six had posterior damage. Repairs of urethral defects were of three types: (1) purse string closures, (2) linear repairs, and (3) end-to-end anastomosis. The diagnostic methods of choice were suprapubic cystoscopic visualization and urethroscopy. The generous use of sulfonamides and penicillin including penicillin irrigations proved efficacious. The most rapid healing of the urethral mucosa was noted when No. 0000 catgut was used, the fascia being closed with cotton and the skin with fine steel wire sutures. Stilbestrol therapy controlled postoperative erections without sequelae. Urethral catheters were removed after from 7 to 10 days and dilatation was carried out within 1 days. In most cases postoperative strictures did not prove troublesome.

Four of the 36 wounds of the bladder occurred as the result of blast injuries. All 4 patients had some degree of hematuria, frequency and urgency of urination. Cystoscopy revealed numerous punctate hemorrhages in each case. With conservative therapy the 4 patients developed normal urine and the frequency subsided.

Although only 6 cases of ureteral wounds have been reported by the author, he believes that these injuries were of frequent occurrence but that the majority of patients did not reach the general hospitals. It was noted that all patients had bowel perforations but in only one case was the diagnosis made at the original operation for repair of the bowel injury. In the other cases the condition was not recognized until fistulas developed. The partially torn ureters healed over indwelling catheters, but complete division required end-to-end anastomosis or nephrectomy. Subsequent ureteral dilatations were necessary.

There were 48 patients with wounds of the kidney including 38 with penetrating or perforating wounds,

8 with renal contusion and 8 with blast injuries. All wounds were repaired or managed in the conventional conservative manner. The 2 patients with contusions of the kidney developed flank tenderness and microscopic hematuria, but healing occurred without sequelae. The 8 patients who had received blast injuries had costovertebral angle tenderness and hematuria. excretory urograms were normal. None of the patients had any localized trauma to the renal area. All recovered with bed rest and without sequelae. Twelve per cent of the 48 patients who had renal injuries required nephrectomy.

PETER L. SCARDINO M.D.

Functional and Morphologic Reactions of the Urinary Tract during the Course and Wane of Nephritic Colic (*Les réactions fonctionnelles et morphologiques de l'appareil urinaire au cours et au déclin de la colique néphrétique*) Jacques Milchon. *J. urol. méd.*, Par 1946-1947 53 201

Tabulated data of 33 cases are presented to illustrate intravenous urographic studies of the functional and morphologic reaction of the urinary tract to nephritic colic. The changes in the urogram are shown during the attack of pain during subsidence of the attack and the 2 following days and from 3 to 20 days after the attack. A control urogram was taken in 19 cases. The results all tend to confirm the spasmodic nature of nephritic colitis. The reactions noted included secretory changes as manifested by the absence of an image and fall of the concentration and reactions of the excretory passages either in the form of hypertonus and hyperkinesia, or in the form of lowered tonus and generalized or localized dilatations. The nephrograms demonstrate complete or partial invisibility of the usually hypo-

tonic excretory passages. The sequence of disorders was found to be as follows during the attack there was no image and the nephrogram (opacity of the excretory passages) was total and during the decline of the attack there was hypertonus and hyperkinesia of the excretory passages (with or without partial nephrography).

The following interpretation of these findings has been suggested

1 Total opacity of the nephrograms indicates stasis due to spasm of the calices and papillary sphincter

2 Absence of images may signify either an equivalent of the total opacity of the nephrogram but with a concentration too low to be visible or a temporary inhibition of the secretion due to an inhibiting sympathetic reflex.

3 The hypotonias and dilatations are secondary phenomena due to muscular fatigue following spasm

4 The partially opaque nephrograms in a state of hypotension indicate stasis due to poor function of the muscles of the excretory apparatus.

The practical conclusions to be derived from these studies are as follows

1 Dilatations following nephritic colic are not lasting and their presence is no indication for operation

2 The absence of the image, i.e. exclusion of the kidney cannot always be labeled systematically. The cessation of secretion is nearly always temporary and reversible so that this sign, likewise, is not an operative indication.

3 The urographic aspects (absence of secretion opaque nephrograms dilatations) are often quite typical enough to permit diagnosis in cases of invisible calculi or sand.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS MUSCLES, TENDONS, ETC.

The Initial Lesions in Acute Osteomyelitis (Les lésions initiales de l'ostéomyélite aiguë). Jacques Lereboullet *Rev orthop* Par 1947 33 77

The initial lesion in osteomyelitis is usually localized around the nutrient artery or its principal branches. The focus is surrounded by a zone of inflammatory reaction localized in the haversian canals, adjacent to a healthy zone. There is usually some periosteal reaction. Initially, the medulla is also affected and directly involved in the pathologic changes.

Acute osteomyelitis of the femur and tibia is discussed in detail, and roentgenograms and reproductions of microscopic sections of diaphyses which were resected when acutely affected with osteomyelitis are illustrated in the original article.

In adolescents, osteomyelitis localizes in the diaphysis or at the junction of the diaphysis and the metaphysis. If localized in the diaphysis it is found around the nutrient artery. If closer to the metaphysis it surrounds the main inferior or superior branch of the nutrient artery. These facts have been demonstrated on roentgenograms. Sometimes the diaphyseal type of osteomyelitis subsides without affecting the metaphysis. This is cited as proof that the initial lesion usually is localized in the vicinity of the nutrient artery. Acute osteomyelitis confined to the metaphysis is considered to be a benign form since a considerable number of cases do not go on to supuration. In the beginning the lesion is located around the main branch of the nutrient artery and often heals before it alters the bony structure sufficiently to permit visualization on the roentgenogram. In case rarefaction occurs it is usually localized at a site where the cortex is thinned. It usually disappears without leaving any trace of destruction.

Pathologic studies reveal that the major changes occur where the nutrient artery enters the bone. At this point, however, the cortex is very thick, which explains the fact that it takes a considerable period of time before the process reaches the extraneous structures. This also is the usual place for the development of sequestra. The clinical signs of osteomyelitis are preceded by the penetration of the abscess underneath the periosteum and rupture into the surrounding soft tissues. This fact is well demonstrated in the rare cases of central osteomyelitis in which a great portion of the medulla is involved with hardly any clinical manifestations. On the other hand, there are cases in which a large subperiosteal abscess is associated with only a small osseous lesion. These facts were discovered at operations in which a portion of the diaphysis was resected.

These findings help clear up the old controversy whether trauma is the cause of acute osteomyelitis.

A trauma can cause the break through of a small cortical abscess into the soft tissue which, of course, is followed by clinical signs. According to the violence of the organism and the resistance of the host, the infection may spread by way of the haversian canals farther up and down into the diaphysis and eventually reach even the metaphysis. The abscess may break through the cortex at any one of these points. These abscess formations have to be considered as secondary foci. The medulla may also be affected eventually, i.e. in the metaphysis. As mentioned previously it has the power of limiting the infection by the formation of zones comparable to the abscesses formed in the soft tissues.

All the evidence points to the fact that the majority of the sequestra are formed in the center of the diaphysis where the osteomyelitic lesions are most serious and the atrophylococci toxins the most active. Histologic examinations showed that the medulla was intact at the level at which the sequestrum was found.

Thrombosis of the nutrient artery alone cannot be made responsible for the formation of a sequestrum. The elimination of the nutrient artery of a bone (in an infant only) like in Ollier's operation or in cases in which entire periosteum covering the bone is scraped off to obtain increased growth of the bone, never gives rise to the formation of a sequestrum. A disturbed blood supply in the presence of infection contributes to the necrosis of bone.

The study of osteomyelitis has been impeded by (1) emergency blind drilling of bone which only adds insult to injury and (2) superimposed infection by too frequent dressings, or by the lack of a dressing once a draining sinus has formed.

The fact that acute osteomyelitis does not localize initially in the bulbous portion of the bone and that the medulla so frequently is free from infection definitely condemns the so-called emergency drilling of bone. Early resection of the diaphysis is contraindicated since the surgeon is never able to evaluate the actual destruction of bone because it does not correspond to the degree of soft tissue involvement. Finally it is important to realize that penicillin should be injected locally because it is unable to reach the focus of infection if given intravenously. The nutrient artery usually is thrombosed and the periosteum is separated from the bone in the areas of infection.

Many workers believe that the nutrient artery does not play an important part in the metabolism of bone. The nutrient artery supposedly is important in the development of the bone but loses its significance after birth. It can be assumed that in certain cases the artery remains patent allowing organisms circulating in the blood to settle there and cause the development of osteomyelitis.

GRODINSKY I. RABIN, M.D.

Treatment of Acute Osteomyelitis with Penicillin
 Report on 30 Cases (A penicilina no tratamento da osteomielite aguda) Flavio Pires do Carmo
 and Enrico Toledo do Carvalho *Rev Hosp Clin* 1947 2 1

Treatment of acute hematogenous osteomyelitis with penicillin prevents the formation or causes the dissolution of metastatic foci and causes the disappearance of the primary osseous lesion within 3 or 4 weeks in approximately 90 per cent of the cases. To obtain such results the treatment must be instituted early the dose must be adequate the medication must be continued for a sufficiently long period of time and the periosteal and metastatic abscesses must be drained.

The following steps are recommended by the author:
 1. Immobilization of the affected extremity in a splint for from 30 to 50 days.

2. General treatment consisting of daily intravenous administrations of from 1,000 to 2,000 c.c. of glucose or saline solution to combat dehydration toxemia, and acidosis; daily transfusions of from 200 to 500 c.c. of blood to fight bacteremia and secondary anemia; a high carbohydrate diet and the administrations of vitamins.

3. The administration of 15,000 units of penicillin intramuscularly every 3 hours, the total dose ranging from 1,000,000 to 5,880,000 units according to the patient's resistance; virulence of the micro-organisms and the time the treatment was initiated. The administration of penicillin is stopped 2 weeks after the return of the temperature and the leucocyte count to normal levels. Abscesses in soft parts are aspirated every third day and 5,000 units of penicillin are injected. The administration of penicillin is supplemented with from 20 to 30 gm. of sulfonamides.

When these rules are observed general and local clinical symptoms disappear rapidly; this is in contrast to the roentgenologic signs which persist a long time. This is due to the fact that penicillin transforms a septic necrosis into an aseptic one. The sequestrum acts like an autogenous graft, which requires a certain time for its rehabilitation.

The authors report 30 cases of acute osteomyelitis in which early institution of treatment with penicillin and the administration of sufficient doses prevented the development of a chronic form and avoided the necessity of an operation. JOSEPH K. NARAY, M.D.

Eosinophilic Granuloma of Bone. Robert N. Cooley and Glenn D. Carlson. *Texas J. M.*, 1947 43 64.

Ten cases of eosinophilic granuloma of bone have been observed by the author in the past 3 years. The symptoms include aching "bone pain" in the region of the lesion; localized tenderness which gradually subsides; localized soft tissue swelling, at first hard and tense with subsequent softening. Constitutional symptoms are usually absent although a low grade fever and leucocytosis may be present.

Eosinophilia was found in only 1 of the 10 cases. The sedimentation rate was found to be elevated in 3 patients who were in an early acute stage. It was

normal when ascertained in a chronic or quiescent stage. The roentgen picture is of a round or oval bone defect with a smooth margin and no bone reaction. The ribs and skull are most frequently affected, with less common involvement of the pelvis, shoulder girdle, long bones and vertebrae. Periosteal reaction may be seen in the ribs and long bones, and fine trabeculation may occasionally traverse the bony defect. The rate of growth may be quite rapid. Healing following roentgen therapy requires from 6 months to 3 years. No fatalities have been reported from eosinophilic granuloma.

The tissue found in these bony defects closely resembles that of the Schuller-Christian syndrome both grossly and microscopically. However, the 2 diseases run quite different courses.

The best results of treatment probably follow a combination of surgery and irradiation.

VERNON C. TURNER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Experiences in the Use of Cellophane as an Aid in Tendon Surgery. A. W. Farmer. *Plast Reconstr Surg* 1947 2 207.

The author in attempting to prevent adhesions by interposing cellophane between the gliding surfaces has met with varying results, and he presents the unsuccessful cases as well as those which turned out well. His interest in and study of this material began in 1932 and included numerous animal experiments. He has found that completely surrounding a great length of tendon with cellophane has resulted in necrosis and finally rupture of the tendon due to tension. The blood vessels were unable to reach the tendon and necrosis was the result.

On human subjects, since 1936 the procedure has occasionally seemed indicated when the transmission of power from the muscles to the fingers was almost or completely restrained by adhesions. No 300 cellophane was selected as the best material.

The anatomy of the flexor tendons of the digits of the hand is discussed and the fact that the reflections of the sheaths on to the tendons carry the blood vessels is pointed out. The most common disabling injury to the flexors of the fingers and thumb is damage to the sliding mechanism in the area from the proximal transverse palmar crease to the distal digital crease. This results in the loss of the ability to flex the interphalangeal joints. Adhesions between the tendon and sheath in this area completely eradicate function, as this part of the sheath is firmly adherent to the bones and in some positions to the annular ligaments. The metacarpophalangeal joints can be flexed fully because the interossei and lumbrical muscles accomplish this motion and it is not dependent upon the sliding mechanism of the long flexor tendons. Five cases are presented to illustrate the varying results obtained.

1. In the first case the fifth finger flexor was surrounded by cellophane. The operation failed because

cause the skin was not well closed and drainage caused the removal of the cellophane and failure of the surgery.

2 In this case the index finger flexor was freed and a slip of cellophane was placed beneath it. The tendon was not surrounded. This resulted in normal function promptly.

3 All the flexors in a mass had become adherent and a large sheet of cellophane was placed beneath them. This resulted in great improvement in the total function of the hand but, of course, in no individual function of the tendon.

4 The index finger flexor was freed and a slip of cellophane was placed beneath it. No improvement was accomplished.

5. A slip of cellophane was placed beneath the freed fifth finger flexor and practically normal function was obtained as soon as motion was permitted.

The poor results are probably due to adherence of the tendon to the ends of the cellophane implant, and the author suggests the use of a longer strip of such implant than seems necessary extending it to the tendon insertion.

Good results have usually been apparent early and once obtained they have continued to be good. Poor wound closure was the cause of some poor results. Firm healing of the surrounding tissues must be obtained before motion is permitted.

NEWTON C. MEAD, M.D.

The Use of Absorbable Substances to Obliterate Bone Cavities and as Hemostatic Agents in Operative Procedures on Bones and Joints.
Joseph Buchman and John E. Blair. *J Bone Surg* 1947 29 630

In the treatment of chronic osteomyelitis, the authors have resorted to the primary closure of wounds resulting from the surgical procedures. They have used a technique consisting of the intramuscular administration of penicillin at 3 hour intervals for approximately 24 hours prior to a thorough saucerization of the osteomyelitic focus (under tourniquet control, whenever feasible) and the removal of all diseased and scarred overlying soft tissues. After the proper toilet of the wound with saline solution the cavity is flooded with normal saline solution containing 250 units of penicillin per cubic centimeter of fluid. The wound is then firmly closed in several layers without drainage. Adjacent sinus tracts are excised, whenever possible, and closed without drainage. If such a procedure is not feasible, the tracts are curetted and their openings are sealed with several sutures. Gauze soaked in penicillin-saline solution is used as a dressing and the parts are immobilized in a huge compression bandage of sheet wadding flannel bandage, and adhesive tape. The intramuscular administration of penicillin, started on the day before the operative procedure, is continued uninterruptedly for a period of from 10 to 24 days after operation according to the patient's range of temperature and upon the character of the healing of the wound. The dosage of penicillin varies, with

the sensitivity of the micro-organism to the antibiotic. In those instances in which the organisms are sensitive to 0.5 unit or less of penicillin per cubic centimeter, 50,000 units per dose are ordinarily given. When the micro-organisms are resistant to 0.5 unit or more, 30,000 or 40,000 units per dose are given. The concentration of the penicillin used locally in all instances, been 250 units per cubic centimeter of normal saline solution.

The treatment of chronic osteomyelitis by saucerization and primary closure of the wound under antibiotic influences has brought with it the problem of control of the hematoma which develops in the resultant bone cavity. It has further been noted that if the hematoma is too large to be organized rapidly a sinus results. The authors noted some delay of bone repair in the series of cases. This was in keeping with the findings in animal experiments by Lister and Frantz that absorbable gelatin sponge (gelfoam) showed a slight delay in healing of fractures as compared with those treated with fibrin foam. There seems to be little doubt that the presence of oxidized cellulose in the immediate vicinity of a fracture interferes with the normal processes of repair of bone.

The technique of the use and manufacture of gelfoam and oxycel, the operative procedure, substances used for hemostasis and filling of the cavity and various remarks concerning the case histories are given in tabular form. The use of oxidized gauze or absorbable gelatin as a vehicle for thrombin and penicillin in filling dead spaces or bone cavities appears to be inadvisable, from the authors' limited experience because of the large number of complications which interfere with the healing of the surgical wound by first intention. The use of oxidized gauze or absorbable gelatin with thrombin as hemostatic agents in the presence of troublesome oozing and bleeding is advisable, and at times invaluable notwithstanding the fact that the final healing of the wound may in a considerable proportion of instances, be delayed by temporary partial disruption incidental to the evacuation of collections of blood serum. The clinical difference in the character of the healing has led the authors to abandon the use of oxycel and gelfoam as fillers for bone cavities.

C. FRED GORDON, M.D.

Flexor Tendon Grafts to the Finger and Thumb.
Walter C. Graham. *J Bone Surg* 1947 29 553.

The loss of the flexor tendon to a finger or thumb greatly handicaps the function of the hand and especially involves the loss of pinch hook grasping and holding of objects by the involved digit. The most logical treatment is restoration of the flexor tendon function to the digit. When a flexor tendon has been cut for some time, the proximal end will retract, so that it is impossible to do an end-to-end anastomosis. The author reports views based on experiences with 141 flexor tendon grafts.

Tendon grafts are transferred primarily and no attempts to establish preformed sheaths were made in this series. The tendon graft is dissected out from

its donor site with the surrounding gliding mechanism intact. Pulleys are used in sites where the transferred tendon might bowstring. Tendons are not laid over bony surfaces. Considerable freedom is allowed in the new sheath to avoid necrosis and adhesions during the healing stage.

Not all fingers with lacerated tendons are amenable to grafting. Primary consideration should be given to sensation. An extensively scarred finger does not lend itself to tendon repair. It is often preferable to fix the distal interphalangeal joint and insert the new tendon into the middle phalanx. It is most difficult to restore flexor tendon function in the little finger. Generally attempts at repair should be made only when it is an occupational necessity. As a rule, the sublimis tendon is excised and the profundus tendon assumes the control of the distal joints of the finger. A tendency for the proximal interphalangeal joint to go into hyperextension is avoided by fixing the stump of the sublimis tendon across the proximal interphalangeal joint into the proximal phalanx with the joint held in about 10 degrees of flexion. In cases in which the laceration is distal to the proximal interphalangeal joint the sublimis function can be retained and a graft can be extended to the distal phalanx and fixed proximally to the stump of the profundus tendon. The finger joints should move as freely as those of a normal finger before a graft is attempted. An effort should also be made to restore the muscle tone as it is extremely important that sufficient motor power be present to mobilize the tendon through the sheath.

The most accessible and frequently used graft has been that from the palmaris longus. Often the excised sublimis tendon will serve. The long extensor tendons of the toes are available but have the tendency to fray on handling. The peroneus longus or plantaris muscle tendons may be used. Precaution should be taken to avoid use of too large a tendon that will become necrotic in the center and cause more local reaction and thus adhesions. Occasionally tendons from other individuals have been used satisfactorily.

The site of suturing a tendon graft is extremely important. Suture should never be made between the proximal interphalangeal crease and the distal palmar crease. Distally the graft may be sutured to the stump of the profundus tendon or into the distal phalanx. Proximally the suture line should lie in the base of the palm or above the wrist.

The procedure of tendon grafting first includes excision of scar tissue and the stump of the old tendon. In many cases it is necessary to transfer flaps to scarred areas prior to operation for tendon grafting. The author reports better results by fixing the distal end of the tendon graft into the phalanx according to the Bunnell technique with pull out wire. Proximally Bunnell techniques of pull out wire or silk suture are satisfactory. In the base of the palm, the suture line is wrapped with the sheath of the lumbricalis.

In a flexor tendon graft to the thumb the graft is fixed distally with a pull out wire and the proximal

suture line is well above the wrist. If there is extreme scarring in the base of the palm, threading of the tendon outside of the carpal canal may be done.

Frequently advanced atrophy of the muscle unimproved by preliminary strengthening exercises leads the author to substitute a healthy muscle for motor power. He cites use of the sublimis tendon of the ring finger to motivate the index finger, middle finger or thumb. Muscle switching can be carried out without jeopardizing the function of the donor finger.

The most important part of flexor tendon grafting comes after surgery has been completed. The hand and wrist are splinted for 21 days. During the fourth week gentle active and passive motions are instituted. After 4 weeks moderate resistive exercises are instituted and in 6 weeks flexion against resistance is encouraged.

The technique of freeing the flexor tendon graft in its newly formed sheath is extremely important. Each joint should be held individually and forceful active flexion should be encouraged. This should not be done in less than 6 weeks after the operation. In practically all instances a snap will be felt as the tendon is freed in the sheath and an increase in the flexion function will be noted immediately. If the function of a graft has not been restored in 8 weeks the prognosis is discouraging.

Operative tendolysis by stripping the tendon after 6 or 7 weeks frequently will restore considerably more function. If either the distal or proximal suture line pulls apart, immediate regrafting gives gratifying results. When patients are reluctant to put sufficient flexor pull on the grafted tendon because of pain, infiltration ulnar or median nerve blocks are instituted to promote vigorous flexor muscle exercise. This frequently is done after 4 weeks. Occupational therapy has been very helpful in aiding in the restoration of function.

KEMATH H. SPONSEL, M.D.

The Surgical Treatment of Osteoarthritis of the Hip Joint Herman G. Gado *Acta chir scand.*, 1947 95 Supp 120.

This monograph is based on clinical observations during and after operative treatment of 123 osteoarthritic hip joints. There were 115 patients on whom 130 operations were performed during the period from 1938 to 1946. The operations were listed as follows:

- 15 capsular extirpations as an independent intervention
- 14 arthroplasties with Smith Petersen vitalium cap
- 49 arthroplasties with vitalium cap and capsule extirpation
- 7 arthroplastic resections
- 12 shelf operations
- 6 acetabuloplasties
- 27 arthrodeses
- 3 drillings and bone transplantations to the head or neck of the femur

INTERNATIONAL ABSTRACTS OF SURGERY

Three patients (3.3%) died. The causes of death were pulmonary embolism, fat embolism and paralytic ileus 1 case of each. Two patients died subsequently of intercurrent disease. Of the 115 patients 44 were men and 71 were women. The average age was 45.5 years. The affection was unilateral in 50.8 per cent and bilateral in 49.13 per cent. Of the 123 hip joints operated upon for osteoarthritis, 47.9 per cent presented congenital dysplasia of the hip joint. In 14.5 per cent the etiology was unknown. In the remainder of the cases the affection had developed on the basis of trauma, epiphyseolysis Legg-Calve Perthes disease, aseptic necrosis and nonspecific arthritis. Cases of osteoarthritis which developed on the basis of chronic polyarthritis were not included.

Capsule extirpation as performed by the author is indicated in the earlier cases before there is great deformity of the joint surfaces. The degree of excision of articular cartilage seems to play a less significant role for the immediate therapeutic result. The operation is contraindicated in the cases in which there is subluxation or a tendency thereto. Thus operation is not suitable for very old or very debilitated patients.

The technique employed by the author in his capsule extirpation operation is essentially that of Smith-Petersen. The incision is carried farther backward in order to facilitate the excision of the posterior portion of the capsule. The muscles are detached from the ala illi extraperitoneally in order to decrease undesirable new bone formation. The tendon of the rectus is retracted while the hip is held in 30 to 45 degrees of flexion. In difficult approaches the tendon is sectioned. The fibrous capsule is separated from the overlying muscles. This may be accomplished largely by blunt dissection. The capsule is then detached from the acetabulum and downward toward the neck, but a collar of capsule is permitted to remain on the neck in order to preserve the blood supply. When as much of the capsule as possible has been removed through this anterior approach the head of the femur is dislocated from the acetabulum by adduction and external rotation. A strap traction the remaining portion of the capsule is placed around the neck of the femur and by lateral thrust. Protruding bony excrescences are resected. The head is replaced in the acetabulum. The gluteal fascia is securely reattached to the iliac crest. A drain is used for 24 hours to prevent hematoma formation. After the operation the extremity is placed in semiflexion and slight abduction over a large pillow. After a week, passive and active motion of the hip joint is begun, and at the end of the second week the patient is up and about on crutches.

The technique of vitallium cap arthroplasty described by the author is similar to that of Smith-Petersen arthroplasty. Grade of articular cartilage as possible deeper type of cap is preferred. Once active movements of the operation started under the supervision of a

therapist. The first 4 to 6 weeks are the most important in re-establishing movement. The exercises no complicated suspension or traction apparatus. Exercises are continued for more than a year postoperatively. The patients are taught to walk correctly.

DANIEL H. LAVERGNE, M.D.

The Technique in Transarticular Nailing Arthrodesis of the Hip-Joint. Hugo Aronson, *Ann. Surg.* 1947 95 475.

The author suggests a technique for transarticular arthrodesis of the hip joint. The problem of obtaining a satisfactory end result and the complications which have been reported by other authors are discussed. The most common complications are (1) extrusion of the nail (2) subtrochanteric fracture of the femur (3) diastasis in the joint, and (4) failure to drive the nail home. The author suggests that with careful technique attention to detail, and the use of a Smith Petersen three flanged head and the transverse screw through a rotatable head the desired excellent end results will be attained. It is suggested that with the aid of a Bahr's three-rod chisel, the nail can be easily and neatly driven in without the risk of producing a subtrochanteric fracture of the femur.

Two figures showing roentgenograms of these pins in place and 5 additional figures showing the preparatory drill, V. Bahr's three-rod chisel as the instrument for nail extraction are shown.

FRACTURES AND DISLOCATIONS

Effects of Thrombin Injection into Hematomas Enveloping Fractures of Humerus in Rabbits. E. P. Lasher and G. B. O'Neill. *Archives* 1947 40 36.

An experimental study was made on male rabbits in which the right humerus was broken in a metal clamp. An hour later 1,000 Iowa units of thrombin in 5% c.c. of saline solution were injected along the fragment ends. In one-half of the animals. The Gross and microscopic figures are presented of these lesions at 12 days, 30 days and 35 days. The authors believe that there is suggestive evidence that the local injection of thrombin into the fracture area limits excessive bleeding and results in a more orderly and perhaps more rapid repair of the injury. And that, by inducing early clotting of the blood surrounding the fragments does not impede the eventual restoration of bone continually.

RICHARD J. BENNETT, JR., M.D.

studies of biopsies, the effects of the blood type and Rh factor and the methods used in the preservation and storing of bone. Regeneration in bone grafting takes place only when the grafts are in contact with living bone. Age is important in that grafts have proved to be more successful in the young than in the aged.

Cortical bone is believed best for stability while cancellous bone is preferred for osteogenesis. The blood type has been shown to have no influence on the successful use of homogenous grafts of bone, nor does the Rh factor influence transplantation results. Homogenous bone grafts were used in 67 operations with but 4 complications.

METHOD OF USING AND STORING BONE

1 *Direct or immediate grafting* Bone may be obtained from other patients upon whom operations are being performed simultaneously or from relatives who are admitted to the hospital for this purpose. It may be transferred directly from the donor to the recipient. This method of transfer was used in 15 instances for homografts and in 9 instances for syngeneic grafts.

2 *Delayed grafting* This type of grafting whether autogenous or homogenous, is the storing of bone in the tissues of a patient for use in secondary operations. This method has been used successfully on several occasions, but should rarely be necessary in institutions where a method of keeping a supply of bone in a bank has been instituted.

3 *Refrigeration* This is a convenient method of preservation. For tissue to be used in the human being the temperature and duration of storage are

important. Two methods of refrigeration have been used in the New York Orthopedic Hospital. In regular refrigeration bone may be stored at $+2$ to $+5$ C for periods up to 3 weeks. It is stored under sterile conditions in a glass screwtop container which is placed within a similar larger bottle. The second method is deep freezing at -25 C. The method has been tested experimentally on rabbits and used in 30 human cases. With both types of refrigeration the bone is warmed to room temperature before it is used. Bone which has been preserved under these conditions has the appearance of fresh bone. Homogenous bone grafts have been used in 67 operations performed on 50 patients, with bone from 73 donors. Syngeneic grafts were used in 9 children in operations for congenital pseudarthrosis osteogenesis imperfecta, and large bone cysts. The excellent results obtained in this entire series of patients as well as the minimum complications experienced, have been very encouraging.

Excess bone removed from the ilium during such operations as arthroplasties and fusions of the hip as well as bone from the tibia and from other sources, is placed in the bank. Prior to storage the bone is cleaned. It is cut into small pieces when used. All suitable bone is collected and placed in the deep freezer for future use. The ilium is the best and largest source of cancellous bone the tibia of cortical bone. Homogenous bone may be obtained in large quantities in the future from cases in which trauma has been the cause of death. The bone should be collected and stored immediately after death and the necessary precautions regarding sterility should be observed.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Phlebography for the Study of Obstruction of the Veins of the Superior Vena Caval System. Sol Katz, Hugh Hudson Husey and James Ross Veal. *Am J M Sc* 947 47

The authors note that phlebography, by providing roentgen visualization of the veins, offers a method unequalled by other techniques for defining and localizing lesions of the veins and determining the distribution of the collateral circulation. This method has been used mainly in connection with thrombosis of the veins of the lower extremity. Its importance in similar lesions of the veins of the superior vena caval system has not been emphasized. There has been no report made prior to this which offers a full appraisal of the value and limitations of phlebography in cases of obstruction of the superior vena cava and its main tributaries.

In the present contribution, it is the purpose of the authors to present cases which are illustrative of their experience in lesions of this type and which provide adequate testimony to the value of phlebography as a means for precise diagnosis.

The technique of phlebography in the superior vena caval system is described and a number of case reports are presented. Phlebography provides anatomic details that otherwise could be obtained only by dissection. There is no other means to differentiate clinically obstruction of both innominate veins from occlusion of the superior vena cava, or axillary vein thrombosis from obstruction of the subclavian vein. There is no more accurate method for the study of the development and extent of the collateral venous circulation. Phlebography of this type is very simple, no special apparatus is necessary, and the technique requires only the skill ordinarily employed in a venipuncture. Diodrast is used as the contrast medium and it is believed by the authors, to be almost entirely safe. However it is advised that tests for hypersensitivity of the patient to the drug be per-

The Surgical Pursuit and Removal of a Metallic Foreign Body from the Systemic Venous Circulation. W W Davey and G E Parker *Br J Surg* 1947 34-392.

An unusual case is presented, in which a shell fragment was pursued through the systemic venous circulation and ultimately removed successfully. The patient, aged 19, sustained a shell wound in the left clavicular region. At operation, a small metallic foreign body was removed. Subsequent x-rays revealed the presence of another metallic foreign body in the upper anterior mediastinum. Because of the presence of retrosternal pain, evening temperature elevation, and the possibility of abscess formation or secondary hemorrhage, a second operation was performed. A C-shaped incision was made exposing the second and third left costal cartilages and sternum at that level. The foreign body was felt in the left innominate vein and during the operative manipulation it became dislodged and moved toward the heart. Immediate x-ray examination revealed the fragment to be lying in the right auricle. The operation was continued 1 hour later at which time the pericardium was exposed through a reversed C-shaped incision which incorporated the lower limit of the first incision. The foreign body was felt in the intrapericardial portion of the inferior vena cava. Attempt at removal with a pair of forceps introduced into the auricle was unsuccessful, and immediately following this manipulation the fragment passed down the inferior vena cava to the right common iliac vein. Since there was danger that the foreign body might be drawn back into the heart during coughing or postoperative vomiting, when pressure in the great veins is negative, immediate reoperation was decided upon. Through an oblique extraperitoneal incision parallel to the inguinal ligament, the vein was tied off proximally and the fragment removed. It proved to be a jagged shell fragment, 1 by 1/4 by 1/4 inches.

years, and he is leading a normal life working as a technician in technicolor.

The authors review the literature and present several somewhat similar cases which have been described. They mention Warthen's work on dogs in which he introduced metallic foreign bodies into their veins. In all cases they were carried toward the heart. This occurred in hours or days but the heart was reached, irrespective of gravity or the dog's position. Upon reaching the heart the smaller bodies tended to remain in the right ventricle at the base of the chordae tendinae while the larger ones were carried through to the lungs.

It appears clinically and experimentally that the usual course of a foreign body in the venous system is toward the heart. This tendency can be reversed or impeded by gravity or coughing at which time a reverse wave of pressure is conducted in the inferior vena cava, distally. Free movement of foreign bodies in the inferior and superior venae cavae occurs because of the absence of valves. The foreign body must be prevented from entering the right ventricle because then according to the reported cases death usually occurs. In the attempt to remove a foreign body in close apposition to a great vein it should be trapped if possible by proximal occlusion of the lumen so that the risk of transmission to the heart is eliminated.

ROBERT A. NARATOFF M D

Absorbable Fibrin Tubes for Vein Anastomoses.
Orvar Swenson and Robert E. Gross. *Surgery*
1947 32: 137

The authors note that until the advent of aseptic surgery substantial progress was not made in the field of vascular anastomoses. The most successful methods of restoring continuity in blood vessels may be divided into two general groups: (1) by careful direct suture, and (2) by the use of mechanical devices. In spite of the greatest care with the suture technique thrombosis is a common cause of failure to produce a satisfactory anastomosis.

Various mechanical devices have been used for uniting blood vessels more quickly and more successfully than the suture technique. The history of the use of these and the objections to their use are reviewed by the authors. When the magnesium ring is used, a highly basic salt results and provokes violent tissue reaction. Rigid tubes made of vitallium excite little tissue response. In adults the use of a vitallium tube has provided a satisfactory method for making blood vessel anastomoses. In children this method has certain limitations because the vein lumen at the anastomosis cannot possibly increase in size because of the rigid tube.

Because of this limitation the authors sought for material which (1) would be sufficiently rigid (2) would cause little reaction in animal or human tissues, and (3) would be absorbed by the host in a matter of several weeks or months. Fibrin film was found to be a material that gave a minimum of tissue reaction and was completely absorbed in from 6 to 8 weeks when used in monkeys and human beings.

The investigation reported upon by the authors was made during and after vascular anastomoses with plasticized fibrin cuffs to aid in vein reconstruction by a nonsuture technique. The method of the preparation of fibrin film is discussed and the technique of its use is described. Dogs were used in all of the experiments. The abdominal vena cava or a jugular vein was employed for the various anastomoses. Twenty-seven anastomoses of the veins were made, removed and examined later. Thrombosis had not occurred in any instance. When the vessel was opened the intima was smooth and glistening and the precise line of anastomosis was often difficult to identify. Because of extensive regional infection a vena cava vessel had become obliterated by fibrosis.

In summary, a detailed description is given of the nonsuture method of vascular anastomosis used by the authors, wherein the vessel segments are brought together over a fibrin cuff to make an intima lined reconstruction. The fibrin tubes disappear usually in 6 or 7 weeks. This leaves an anastomosis which is adequate in size, which is not constricted by a metallic ring and which can enlarge in diameter with any subsequent growth of the individual.

HERBERT F. THURSTON M D

Conservation of the Arterial Channel in the Treatment of Arteriovenous Aneurysms (De la conservation de la voie artérielle dans le traitement des anévrismes artério-veineux) René Le Riche. *Lyon Chir.* 1947 43: 139.

The idea of endaneurysmorrhaphy first suggested by Matas has given rise to the present day concept of preserving the arterial channel in the treatment of arteriovenous aneurysms. If the fistula is a narrow tract, it is simple to close each orifice with a suture and cut the fistulous tract. Usually the artery and vein are adherent for some distance proximal and distal to the opening. This makes it necessary to select one of several alternative procedures such as the following:

1. Separation of the union of the vessels and lateral suture of the artery and vein. This is theoretically the ideal procedure since the integrity of the circulation is re-established.

2. Lateral suture of the artery and sacrifice of the vein. This procedure may be carried out when the fistula is difficult to locate but when the vein is ligated the patient may be bothered by persistent edema.

3. Endovenous suture of the opening of the fistula. This is the original Matas-Blickham procedure. The author believes that it is useful chiefly in cases of carotid jugular aneurysm to avoid the danger of hemiplegia which may follow quadruple ligation. In the extremities he believes it is safer to free the artery above and below the fistula then dissect the sac sufficiently to separate the vessels and repair them individually.

4. Endarterial suture of the opening of the fistula. The author cites a single case reported by Robert

Danis (*Act Chir Belg* 1946 p 101) in which this procedure was carried out successfully for an arteriovenous fistula of Scarpa's triangle and the vein was completely covered by the artery.

5. Closure of two adjacent arterial segments by opening the vein and sacrificing it. One case of this type is described in which a small adjacent openings between the posterior tibial artery and vein were closed by transvenous suture. This type of procedure is put forth as preferable to quadruple ligation as the author believes the collateral circulation is poor in the foot. When an arteriovenous fistula has been present for some time the proximal portion of the artery becomes markedly dilated. If the artery is then excised or otherwise obliterated an ascending thrombosis in the dilated arterial tree may lead to gangrene. Thus when the vessels are dilated proximal to an arteriovenous fistula the re-establishment of the arterial continuity is absolutely necessary.

5. End to end suture of the artery and the vein with a graft after excision. This procedure is rarely indicated. Even when the artery itself contains a sac, the author prefers a direct repair of the artery or an endosaccular obliteration of the arterial orifices.

The aforementioned conservative procedures are possible only in the presence of perfect hemostasis. At the roots of the extremities complete hemostasis is to be obtained only by compression of the proximal subclavian artery for the upper extremity and of the aorta for the lower extremity.

When any procedure is performed in which the endothelium is sutured there seems to be a state of vasodilatation distal to the sutured area which stimulates sympathectomy without the anhidrosis which accompanies the latter.

BLOOD; TRANSFUSION

Homologous Serum Jaundice. I Herbert Scheinberg, Thomas D Kinney and Charles A. Jaisway *J Am. M. Ass.* 1947 134 841

The authors are reporting the cases of homologous serum jaundice which were observed in the Peter Bent Brigham Hospital during the year ending August, 1945 to emphasize the importance of this disease and to discuss the problem of serum jaundice and possible methods for its prevention in the operation of a hospital blood bank. In the blood bank which has been run jointly by the Children's Hospital and the Peter Bent Brigham Hospital the blood is collected with the usual safeguards and precautions and stored in sodium citrate at 5 to 10 degrees C. At the end of about 7 days the red cells are discarded and the plasma from 10 to 15 bottles is combined to make a pool. Each pool is numbered, a sample cultured and a record made of the donors whose plasma it contains. The pool is then frozen and stored. When it is to be used the plasma is thawed at 37 degrees C. and divided into 250 c.c. units.

The criteria used in selecting cases of homologous serum jaundice for this report were (1) each patient

had received plasma or blood or both between 34 and 135 days before the onset of jaundice (2) the clinical observations were characteristic of acute hepatitis, and (3) in the fatal cases the pathologic findings were those of fatal hepatitis. Thirteen cases are reported in detail 3 with definite homologous serum jaundice 3 questionable cases, 3 other fatal ones, and 5 other nonfatal cases. As an example, pool Ks 119 is cited in which 7 of 9 individuals given transfusions developed this condition.

It is emphasized that there is no diagnostic test which will differentiate between homologous serum jaundice and infectious hepatitis. The criteria which were used suggest that the former diagnosis is correct but does not prove that the disease was not infectious hepatitis. Also most of these patients were over 30 years of age whereas infectious hepatitis usually occurs in younger persons. In considering pool No. 119, which is cited specifically they investigated the 15 donors for the source of the ieterogenic agent. Twelve gave negative responses. One had confirmed diagnosis of congenital hemolytic icterus, 1 had had jaundice 3 years before, and 1 just before donation of blood reported loss of appetite, nausea, soreness in the right thoracic region just at the last rib, yellow stools, easy fatigability and nervousness. Either of the latter 3 could have been the source. Two patients died of their original disease before sufficient time had elapsed to permit them to contract serum jaundice. Thus 11 cases are chosen as examples of homologous serum jaundice if 3 months is assumed to be the average incubation period of homologous serum jaundice. This study occurred over a period of 1 year. During this period 1,404 units of blood and 949 units of plasma were given to patients in the hospital, and a minimum incidence of the disease could therefore be 1 in every 333 transfusions. It is probable that as a result of the pooling procedure plasma is much more apt to produce jaundice than is whole blood. The minimum incidence would be 1 in every 86 transfusions of plasma if all these cases resulted from plasma. Detection as to the source is extremely complex when a patient has received multiple transfusions involving a large number of donors. Lots of homologous blood products which are definitely ieterogenic vary greatly in the incidence of jaundice following their administration.

The mortality is variable. In the authors cases the mortality was 36 per cent, which they consider abnormally high.

In considering methods of control the authors believe that in the operation of the blood bank greater efforts should be made to detect the infectious donors, the practice of pooling plasma should be curtailed, and lots of plasma should be given to as few recipients as possible. They believe that the following should be excluded as donors. Any person who has (1) ever had jaundice or hepatitis (2) had contact with a person with jaundice in the past year (3) received human blood or its derivatives in the preceding year except products of plasma fractionation, (4) been a hospital patient in the past year (5) had

fever (6) icterus (7) an enlarged or tender liver or spleen or who has (8) bilirubinuria or hyperbilirubinemia.

The basis for condemning the practice of pooling plasma is the fact that the amount of infective serum necessary to produce the disease is incredibly small. They seem to believe that it would be desirable to give the plasma of one donor to only one recipient and no other and thus at least limit involvement to one individual. This would necessitate the requirement that plasma should be typed and crossmatched or treated with group specific substances.

Since the infective principle is extremely potent it is difficult to eliminate it by direct means. Plasma fractionation may be a possible means of elimination. Certainly attempts to treat the recipient preventively have been unsuccessful.

LEROY J. KLENGMAYER, M.D.

Peritoneal Irrigation in the Treatment of Renal Failure Due to Transfusion Reaction H. Cline Robertson and P. S. Rutherford. *J. Lab. Clin. M.* 1947 33: 583.

The reported successful use of peritoneal irrigation for the treatment of renal failure following the administration of sulfathiazole (Frank, Seligman and Fine) prompted the authors to employ a similar method in the treatment of a solitary case of severe renal damage following a blood transfusion reaction. In this instance peritoneal irrigation with Tyrode's solution produced an apparently beneficial effect on the uremic manifestations but the patient died of generalized edema. The authors suggested a modification of Tyrode's solution consisting of a reduction of chloride content with the view of preventing such fatal edema.

LYMPH GLANDS AND LYMPHATIC VESSELS

Experimental Investigations in the Leucemias and the Tumors of the Reticuloendothelial System (Recherches expérimentales sur les leucémies et les tumeurs du système réticulo-endothélial) Maurice Guérin. *Rev. hemat.* 1947 3: 13.

A report is given on the author's experiments at the Cancer Institute of the University of Paris during the last 15 years.

1. Researches on fowl leucemia.

The first investigation was made of the fowl leucemia of Ellerman and Bang, an infectious disease transmitted by a filterable virus. Previously, tumors had been observed in the course of the development of this leucemia, but the reproduction of such sarcomas was inconstant and uncontrolled.

A transmissible erythroblastic leucemia was isolated which seemed capable also of affecting the myeloid and reticuloendothelial elements. Attempts to favor fixation on the reticuloendothelium were made by blocking with India ink or thorotrast by injecting infusorial earth which caused granulomas, and by increasing the virulence of the virus by repeated passage through young chicks. All these were

unsuccessful. However when the virus was attenuated by cold storage with or without glycerin, large numbers of sarcomatous tumors developed in the mesenchymal tissue elements at times even without concurrent leucemia. Histologically these tumors were fibrosarcomas. Some grew rapidly with multiple metastases and others were malignant only in their tendency to recur after excision. The average duration of the course of these tumors was from 1 to 4 months. In a few it was over a year. Some of the secondary tumors were true metastases in that they had the same histological structure as the primary neoplasms but in other cases the secondary growths were histologically new types such as pericardial endothelioma and intestinal myosarcoma. These were apparently not simple cellular emboli but represented a direct action of the virus in which the cytotropism had become modified. No definite epithelial neoplasms were demonstrated.

Working with other strains of hemotropic virus the author and other workers elsewhere have succeeded in producing sarcomas. In answer to the claim that he has been dealing with a mixture of two viruses, he points out:

a. The change in the tissue affinity of the virus is accompanied by a change in the type of leucemia produced.

b. When the virus is subjected to repeated passages through fowl the sarcomagenic power disappears only gradually and leaves the purely leucogenic action.

c. When chickens are immunized against leucemia the virus likewise fails to cause sarcoma, although such immunized animals are still susceptible to other types of sarcoma such as the Rous variety.

Attempts were also made to produce passive immunity by injecting fowl with blood elements or reticuloendothelial tissue suspensions taken from resistant animals. No immunity was produced. Active immunization was produced by progressively larger injections of attenuated virus. Various methods of causing attenuation were tried. The most effective technique for purposes of immunization seems to be the use of formalized leucemic blood incubated at 37° C for from 1 to 4 weeks.

The therapeutic effect of various quinine derivatives was investigated. The best response was obtained with rhodiquin (6 methoxy 8 diethylamino n propylamino quinolin) given in large doses by vein.

2. Tumors of the reticuloendothelial system.

Among 6,000 autopsies on rats the author found 9 cases of leucemia all in females generally of an advanced age. Six of these were lymphatic leucemia and 3 myelogenous leucemia. Of the latter 2 were of the chloroleucemia type characterized by a greenish blue of the kidney, the lymph nodes, and the bony tissues. Transmission experiments with these leucemias were rather unsuccessful except with the chloroleucemias one of which gave rise to a transplantable strain of rat chloroma. After 35 passages the tumor may give as high as 50 per cent of takes. It develops in the region of the implantation

varies in size and may give numerous metastases capable of involving all the organs. Its localization is analogous to human myeloma.

Also like the human affection this disease may be associated with a myelogenous leucemia in its advanced stages. The author likewise considers the green color similar to that of human 'green cancer' of Aran. The pigment exhibits intense red fluorescence under ultraviolet light. Spectroscopic analysis has confirmed the presence of protoporphyrin, but the concentration of the latter does not correlate with the intensity of the green color. Hence, there seems to be some relation between protoporphyrin and the green pigment, although the two substances are not identical.

Among 4,000 rat autopsies, 30 cases of spontaneous lymphosarcoma were observed. Two were of the lymphoblastoma or lymphocytoma type and the others were reticulum cell sarcomas. Implantation of the former was unsuccessful. Three of 7 implantation attempts were successful with the reticulum cell group. Two of the 3 were followed to the seventh and twentieth passage, respectively. Although of the same histological type, the two tumors showed considerable difference in degree of malignancy and sensitivity to roentgen irradiation. At no time did either tumor exhibit leucemic properties.

Among 3,000 mice the author collected 24 cases of reticuloendotheliosis, a growth which generally resembled a diffuse inflammatory granuloma of the reticuloendothelial system but at times manifested itself as a true neoplasm. The mouse disease is compared to certain human affections of the reticuloendothelial system which also seem intermediate between granulomas and true tumors. The author believes the human cases are infections rather than neoplastic since he injected blood from a human case in mice, rabbits and chickens and succeeded in producing two types of disturbance in mice: a paraplegic

syndrome and an abdominal syndrome with hepatomegalia. The spontaneous reticuloendotheliosis of mice were also shown to be transmissible with liver or brain pulp as the source of infection. While some of the infected mice developed a diffuse reticuloendotheliosis, others manifested subcutaneous sarcomas.

From these experiences it is concluded that mouse reticuloendotheliosis seems to be transmissible and in the course of its passage through different animals may undergo alteration from a purely inflammatory granuloma to a neoplasm of the sarcoma type. The etiological agent seems to be infectious but because of the relatively large filter used it has not been determined whether it is a virus or some larger entity such as a bacterium or a spirilla.

By exposing chickens to benzopyrene, leucemia and sarcomas were produced which resembled the spontaneous types but were not transmissible. In rats, sarcomas of the spleen were produced but these also could not be transplanted into other animals. However a histiocytic sarcoma of the liver caused by a benzopyrene implant was transplanted through 5 passages.

The author concludes as follows:

1. The intimate relationship between leucemia and the neoplastic process is apparent in the fact that the leucemic virus was able to cause a sarcoma in fowl, and in rats a myeloma developed from the leucemia. Furthermore, the cycle could be completed by the development of leucemia from these tumors.

2. The existence of the phenomenon of immunity has been clearly demonstrated in fowl leucemia.

3. The transition from inflammatory reticuloses to typical neoplasms such as sarcoma and leucemia has been established.

4. Tumors of the reticuloendothelial system and leucemia have been produced by synthetic chemicals.

THEODORE B. MAXWELL, M.D.

SURGICAL TECHNIQUE

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Digital Foreign Bodies in Spot Welders. W. A. B. Reynard and Frederick Smith. *Brit M J* 1947 1 843

The authors report 12 cases of foreign body in fingers to spot welders. In resistance welding or as it is more popularly known spot welding, two pieces of metal are joined together by a combination of mechanical pressure and the heat generated by the passage of an electrical current. Either a stationary machine to weld small objects or a mobile 'gun' for larger work, is employed in the process. In either type of work, as the current is flowing and the weld is being made, there may be a spraying out ward of sparks of red hot metallic particles. Although this 'splashing' is usually negligible, at some times it is quite appreciable. However it is harmless to an operator wearing adequate protective clothing. It is less likely to be harmful to the operator of a gun for he has to hold the device with one hand and control the flow of current with the other, thus keeping both hands at a safe distance from the site of the weld. Not so with the operator of a machine for such a worker may have his hands close to the electrode to hold the object being welded and change its position from time to time. The worker's fingers are thus exposed to a concentrated discharge of fine metallic sparks travelling at nearly maximum velocity. In the series of cases reported 12 employees all operators of welding machines had multiple fine metallic fragments driven into their fingers.

Essentially these injuries consisted of superficial burns, minute entrance wounds and underlying foreign bodies. The red hot sparks were sterile but carried bacteria and dirt from the skin into the soft tissues, also they coagulated the immediately surrounding tissue and thus set up a medium for the growth of bacteria. The symptoms were primarily those of a burn and later those of retained foreign bodies with chronic inflammation. In no case was there any injury to tendon, bone, joint or nerve. Fortunately the lesions were all localized to the pulp of the fingers. Even such involvement was quite painful and even disabling, especially when there was pressure on the nerve fibrils in the finger tips.

Some of the patients did not report for treatment within the 12 hour period considered safe for primary surgical care. Treatment of their wounds was limited to the application of poultices, incision of small abscesses, excision of necrotic tissue and removal of the small metallic fragments. When the wounds can be treated early the authors advocate thorough débridement under local block of the digital nerves or a general anesthetic through a bloodless field secured by a finger tourniquet with subsequent primary suture. They favor the use of an electromagnet for

more complete removal of the minute metal particles.

The most feasible prophylactic measure appears to be the wearing of protective gloves. Cotton gloves coated with neoprene or asbestos finger stalls worn under the usual cotton gloves have been the most satisfactory to date.

BENJAMIN F. LOVINSKY, M.D.

Infection Caused by *Streptobacillus Moniliformis* Lawrence Kilham. *J England J M* 1947 236 969.

The author reports 2 cases of infection with the streptobacillus moniliformis following rat bites. Typically such infection is characterized by fever, migrating polyarthritides, a skin rash and a relapsing course. Usually a history can be elicited of a rat bite sustained within the preceding 10 days. In the first case that of a 5 month old infant bitten about the face and hand, the causative organism was cultured directly from the wounds and from the blood drawn on admission. However no skin rash or polyarthritides developed, and the wounds healed well despite osteomyelitis of the underlying bones of the hand. Treatment of this case which occurred early in 1940 was apparently symptomatic and largely directed toward good surgical care of the wounds.

The second case was that of a 75 year old man. Three days prior to admission he had been bitten on the forehead. On the day of admission he had fever, chilly sensations, headaches, backache and pains in the knees. The small head wound had healed, and he had no skin rash or evident arthritis. Penicillin was started immediately—40,000 units every 3 hours. Within 1 day the patient had become asymptomatic and within 3 days he was afebrile. Blood drawn on admission and cultured in a meat infusion broth showed within 24 hours the fluffy ball appearance characteristic of colonies of *Streptobacillus moniliformis* and pleomorphic gram negative organisms on smear. Agglutination tests employing the patient's organisms were strongly positive. When the patient's organisms were run against his own serum a marked rise in titer of immune bodies was demonstrated. 10 days after the onset of the disease it was 1:160 and 24 days later it was 1:320. After considerable study Brown and Nunemaker concluded that a titer of 1:80 is diagnostic of infection with the *Streptobacillus moniliformis*.

The author discusses the methods of culturing the organism and points out that the term "rat bite fever" covers 2 separate infections, the one caused by *Streptobacillus moniliformis* and the other by *S. minus*. They may be clinically indistinguishable but both respond well to penicillin therapy. Although the cases reported do not illustrate this fact, one of the outstanding characteristics of infections caused by *Streptobacillus moniliformis* is their pre-

dilation for the synovial membranes with the production of migrating polyarthrititis.

BENJAMIN F. LOEWENBERG, M.D.

The Spontaneous Occurrence of New Bacterial Infections during the Course of Treatment with Streptomycin or Penicillin. Louis Weinstein. *Am J M Sc.*, 1947 214 56.

Five cases have been described in which, during the course of specific antibiotic therapy there developed new infections due to organisms that were not susceptible to the agent with which the primary disease was treated. In 1 patient who probably had atypical virus pneumonia, the administration of penicillin resulted in an overgrowth of *Haemophilus influenzae* in the pharynx, followed by an invasion of the blood and respiratory tract. In another individual, treatment of faucial diphtheria was complicated by the occurrence of pneumonia due to the Friedländer bacillus. The 3 other cases were treated with streptomycin for *Haemophilus influenzae* infections: 1 of these developed bronchopneumonia with bacteremia, another meningitis with bacteremia, and the third recurrent pyelonephritis, all of the conditions being due to the hemolytic *Staphylococcus aureus*.

The mechanism by which this type of infection occurs is not completely clear. However in 4 of the patients there was a remarkable change in the bacterial flora in the nose and throat before new infection developed. Organisms that were apparently present in such small numbers that they were not detected early in the course of the disease increased in number after treatment with penicillin or streptomycin and invaded the tissues. That the new infections were not merely the result of numerical increase of one of the normal inhabitants of the nose and throat was shown by the fact that changes in the nasopharyngeal flora following the use of either antibiotic substance were frequently observed without a resultant new infection. It is possible that in some persons a high degree of bacterial antagonism exists in areas like the nasopharynx and that certain groups of bacteria are kept in check by others. So long as this normal relationship is not disturbed, the numbers and invasive ability of some of the organisms may be kept below a critical level when, however some of the bacteria are removed as a result of contact with an antibiotic agent of high specificity those organisms that are unaffected by the drug increase sharply in number and possibly in virulence. This phenomenon may be due entirely to an increase in numbers of bacteria if the micro-organisms are of sufficiently high virulence. These new infections were seen mainly in young children and in middle-aged adult who had had a serious infection and intoxication for 1 week before antibiotic therapy was started. Age therefore may be a determinant factor. Other factors that tend to produce lowered resistance such as chronic debilitating disease and senility may also be of importance.

The type of organisms normally present in the pharynx is dependent to some degree on the general

distribution of various bacteria in the population during certain seasons of the year. This will determine, in part, the organism that produces a new infection during the course of antibiotic therapy. In example in the summer season the carrier rate for *Haemophilus influenzae* is low and the chance that invasion by this organism will occur as a result of penicillin treatment is less than it is in the winter. The *Staphylococcus aureus* is present in the pharynx of most persons at all times, so that the seasonal factor probably plays only a minor role in the production of disease by this organism in patients who receive streptomycin.

The spontaneous occurrence of new infections due to penicillin-resistant organisms during the course of penicillin or streptomycin therapy raises the question of the use of either of these drugs in instances in which the exact bacteriologic diagnosis is unknown, because patients may be exposed to the added danger of superimposed bacterial disease without any benefit to the primary process. For example, the treatment of virus infections with either streptomycin or penicillin may be dangerous because these drugs have no effect on the primary disease and may allow organisms that are normally present on various tissues and are not susceptible to their activity to grow profusely and invade. The occurrence of this type of secondary infection is a strong argument for limiting the use of antibiotic agents to those cases in which bacterial disease is proved by isolation of the causative agent or to those in which the possibility of bacterial infection is very strong.

Although it might appear that the availability of such agents as streptomycin and penicillin has reduced the necessity for careful bacteriologic studies in patients with infectious diseases, the exact opposite is the case. The highly specific antibacterial activity of these drugs necessitates exact identification of the causative agents of the infections for which they are used, and the need for careful bacteriologic study is greater now than it was prior to the advent of the antibiotic substances. This applies not only to the period of the disease before treatment is started but also to the time during which therapy is being given, lest the manifestations of new infections of the type described in the cases reported be misinterpreted as due to failure of the original disease to respond to the drug being used. Frequent bacteriologic examination of the blood and of the nose and throat of patients who are being treated with an antibiotic agent even though they seem to be progressing well is to be highly recommended because a marked increase in numbers of an organism in the nasopharynx frequently precedes its invasion of the tissues by at least 24 hours. The discovery of a preponderance of *Haemophilus influenzae* or *Staphylococcus aureus* in the nasopharyngeal flora during the course of penicillin or streptomycin treatment should put the physician on guard for a complicating infection due to either of these organisms, particularly if the patient is a young child.

Since new infections may occur spontaneously during the administration of penicillin or streptomycin

in the question may be raised whether or not these 2 agents should be given simultaneously to patients who are particularly susceptible namely the very young or very old, or those with chronic debilitating disease. The combined use of the antibiotic drugs in shotgun fashion with the implication that bacteriologic examination is then not necessary can only be denied. Although each of these agents is on the whole, nontoxic, certain patients may become sensitized to them to the point where they cannot be used. Treatment with a combination of both drugs with an untoward sensitizing reaction may preclude the use of either agent some time later in the patient's life when his survival may depend on it. To advocate the employment of a combination of penicillin and streptomycin would result in even greater misuse of these drugs than they are at present subjected to and would only further their use in many diseases in which there is no infectious basis.

ANESTHESIA

Neurological Complications After Spinal Anesthesia, and Results from 2,493 Follow Up Cases
Gunnar Thorsén. *Acta chir scand* 1947 95
Supp. 121

The purpose of this 272 page monograph has been to ascertain whether complications in the central nervous system occur immediately or later after spinal anesthesia. It submits spinal anesthesia to a critical review, analyzing the results arrived at as well as the risks and indications of the method. It attempts to systematize all spinal anesthesia injuries to the central nervous system and discusses the mechanism of these injuries. The work is based on 2,493 questionnaires filled in by patients subjected to spinal anesthesia, as well as on 100 similar forms answered by patients who have undergone only lumbar puncture. The main part of the material has been obtained from the surgical department of the Central Hospital in Örebro, Sweden. Also a compilation has been made of cases from the literature with complications in the central nervous system after spinal anesthesia. In addition supplementary examinations and experiments on subject material have been performed. Only 2 anesthetics were employed in the interrogated cases viz. percain 1/15,000 or novocaine in the form of a substance or in 5 per cent solution. In addition pontocaine was used in a few cases. Cases with positive Wassermann tests were excluded. The questionnaires were sent out during 1940 up to and including 1943 to 3,375 patients who had been given spinal anesthesia from 6 to 18 months before and in 1945 to 120 patients submitted to lumbar puncture during the previous year.

The types of complications have been distributed in the following way:

1 Injuries localized in the cerebral region. These include headache dizziness disturbed vision uncharacteristic symptoms with possible cerebral cause

manifest cerebral injuries occurring in direct or in close connection with spinal anesthesia or occurring after an interval free from surgery and mental disturbances

2 Injuries localized to the medulla and its covering parts due to trauma, infection or the anesthetic agent

3 Injuries having no connection with the spinal anesthesia.

The material disclosed

1 That complications of the central nervous system occur after spinal anesthesia with the technique employed nowadays

2 That these complications have a far higher frequency than is generally assumed

3 That certain special injury types can be distinguished in which the cases in each separate type show agreement as regards onset symptomatology and course

4 That animal experiments and clinical experience render likely the occurrence of certain mechanisms of origin with regard to these different injury types

5 That certain conclusions may be drawn regarding the prophylaxis and therapy of these injuries.

6 That more strict indications for the use of spinal anesthesia should be stipulated.

MARY KARY M.D.

An Examination of the Local Anesthetic Action of Some Synthetic Sweet Substances and Other Phenyl Alkyl Derivatives. Leroy Vandam and Austin Lamont. *Anesthesiology* 1947 8 390.

It had been observed that some synthetic sweet substances possess local anesthetic properties and the authors thought that such substances deserved further investigation for possible clinical application. The anesthetic activity of several phenyl alkyl derivatives was observed on the rabbit cornea and compared with that of cocaine but none of these compounds proved to be as efficient as cocaine. In addition there were certain unsatisfactory characteristics with regard to solubility pH and color which might preclude the use of the drugs for clinical purposes.

MARY FRANCES POT, M.D.

Anesthesia Narcosis with Vinyl Chloride. Robert H. Oster, C. Jelleff Carr and John C. Krantz. *Anesthesiology* 1947 8 359.

Vinyl chloride gas an industrial chemical has been studied as an anesthetic in the dog. These observations conform to previous data which show that there is little difference in potency between the saturated and the unsaturated analogues, and actually ethyl chloride appears to be the more potent. The anesthetic syndrome is marked by incoordinated muscular activity in the extremities. The recovery period was prompt but accompanied by violent excitation. All of the animals manifested marked changes in cardiac rhythm in surgical anesthesia. These cardiac arrhythmias were of a serious nature

It is the opinion of the authors that as an anesthetic in the dog, vinyl chloride is unsafe and that its use in man is unwarranted.

MARY FRANCES POZ, M.D.

Neurophysiology of Respiration during Surgical Anesthesia. Pneumographic Studies on the Human Being during Intravenous (Pentothal), Ether and Spinal Anesthesia. James C. McCann. *Current Res. Anesth.*, 947 26 89, 140.

These studies have evolved the picture of a complete neurospecific pattern for reflex stimulation of respiratory centers during surgery. Respiratory response to surgical trauma has been demonstrated to be segmentally neurospecific and to occur whatever the anesthetic agent used. In general selective reflex stimulation of either inspiratory or expiratory neurons and intensity of response are directly related to the neurologic segment as well as to the autonomic plane or the structures within which the stimulus is originated.

Reflex response of these accessory muscles of respiration is of both a tonic and a superimposed rhythmic type of contraction. The first is completely independent of and dissociated from the rhythmic respiratory cycle. The second type is a succession of intermittent rhythmic, forceful contractions of accessory muscles during the expiratory phase of respiration. There may be a tonic contraction of accessory muscles of respiration during the induction phase of anesthesia and also as a reflex response to surgical trauma.

The intensity of respiratory response to trauma reveals an increased gradient of activity from the periphery of the body toward the central zone. This is true in both somatic and visceral planes. Reflex response of respiration to trauma as noted in these studies is dependent on stimulation of the end organs which lie in relation to nerve endings in areas having representation of nerves from specific neurologic segments.

Noxious impulses initiated by the trauma of surgery are conducted centrally over two distinct afferent sensory nerve fibers—the somatic and the visceral. This review has outlined the tract of afferent pain conducting fibers from the somatic and visceral regions into the medulla oblongata, but they come into proximity with the respiratory center which results in reflex activation of the respiratory mechanism. Alterations in respiration induced by surgical pain impulses initiated either in somatic or visceral regions represent, undoubtedly, reflex phenomena produced by complex circuits between the center and peripheral areas. These reflexes must be based on rather complex circuits to account for the variable responses.

Pneumographic studies of respiration during surgical procedures on the human being in all portions of the body are presented to demonstrate the essential character of the response. The pattern can be rationally integrated with the existing bodies of anatomic, physiologic, and clinical facts. Its importance is that it constitutes essentially the physiology of surgical anesthesia. MARY FRANCES POZ, M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Diagnostic Value of Tomographic Exploration in Surgery of the Spine (Exploration tomographique du rachis sa valeur diagnostique en chirurgie) Herdner *Rev. orthop. Par.*, 1947 33 341

Following a brief discussion of the advantages of tomography as a supplement to roentgenography in the diagnosis of certain lung conditions the author emphasizes the value of tomography in diagnosis of surgical lesions of the spine. He compares roentgenographic and tomographic findings in the cervical dorsal and lumbar spine. It is now his custom to make a preliminary x-ray examination, to be followed, when indicated by a tomographic analysis for dissection of the region and a minute analysis to overcome the inadequacy of the preliminary roentgen findings.

If pain is located in the medial or inferior apophyses of the cervical spine an analysis of the cervical spine as a whole in a series of 3 sections (median right, and left lateral (all anteroposterior and parallel) will suffice. The results obtained will resemble those seen after dividing the cervical trunk into 3 sections by 2 cuts along the flanks of the vertebral bodies, 1 slice including only the vertebral bodies and spinous apophyses the 2 other slices including the lateral apophyses. Paramedian sections very close to the sagittal plane will show the details of the walls of the spinal canal. Tomography has the advantage over roentgenography in that it reveals intrasections which are indispensable for early diagnosis in the dorsolumbar section but also of interest in the cervical segment. Lateral sections reveal only pedicles, transverse apophyses and articular apophyses on the same side. Tomography shows that interarticular lines may on occasion be fan shaped. A tomogram is shown with destruction of the interarticular line between the axial apophyses and the subjacent vertebra, in a case of arthritis sicca following fracture of the odontoid caused by a fall.

The superiority of the tomographic method is most clearly demonstrated in diagnosis of suboccipital lesions. The occipital condyles can be clearly demonstrated without occipital or maxillofacial obstacle. Also, the lateral masses of the atlas the occipitoatoid interlines and the lateral atloido-odontoid articulations can be seen. The occipital condyles will show even more clearly with greater flexion of the head. The occipitoatoid articular facets are only partially visible and tomography alone would therefore not suffice for a diagnosis of suboccipital Pott's disease. Special anteroposterior paramedian sections will show the entire length of the right or left articular facets.

Sagittal section completely separates the odontoid from the masses of the atlas which mask it and shows clearly the atloido-odontoid articulation. It

also exposes the body of the axis and shows the spinal canal. Parasagittal sections 17 to 20 mm. outside the preceding section permit complete isolation of the lateral mass of the atlas. A study of the occipitoatoid interline and lateral view of the occipital condyle is of special value in the early diagnosis of suboccipital Pott's disease. The technique of this procedure is described. The revelation of the occipitoatoid interline is one of the most valuable contributions of methodical tomographic analysis. Rigid technique quick intelligent assistants and perfect apparatus are needed for successful tomography. With these adjuncts tomography can be practiced successfully even on children under 10 years of age.

Horizontal sections reveal the spinal canal encircled by a vertebral ring at various levels. In the highest section the occipital trough can be seen between the mastoids the pneumatization of the latter being especially clear. A section some millimeters below this shows the atlas from above with the grooves of the vertebral arteries and their passage over the upper surface of the posterior arch. Only horizontal sections will show the anterior or posterior arches of the atlas in their entirety. Thus the spinal canal can be explored from one level to another. For accurate diagnosis it is necessary to see and this is possible only by this method.

The disadvantages of roentgenography in the diagnosis of conditions of the dorsal and lumbosacral spine are discussed. Tomography in the dorsal region constitutes only a variant of pulmonary stratigraphy. Because the method is simple and indispensable for correct diagnosis, it is now done as a routine in completing all dorsospinal examinations. Only scoliosis with its confusing projections is a contraindication. An analytical study of fine sections cut optically in the vertebra permits separation of the dorsal segment into its diverse elements. Thus a median section will reveal the point of complementary ossification of the spinal apophyses, a detail rarely observed in the roentgenogram. The first lateral section isolates the articular pedicles and apophyses on one side only and the second more external lateral section reveals the transverse apophyses and vertebral extremities of the ribs. Thus for all levels of the spine tomography permits two types of section, i.e. those of dissection showing the general morphology and those of intrasection exposing the interior of the bone. In a case of Pott's disease in which the carious focus as seen in the roentgenogram was masked by bronchial markings tomography permitted demonstration of the location and extent of the caries. Tomography has also been of aid in demonstrating vertebral metastases in cases with negative roentgenologic findings. Tomography was found useful in detecting foci of osteoarticular tuberculosis and is the only method permitting correct projection in profile of the first dorsal vertebra. Even

a faint tomogram yields more information than an excellent roentgenogram, and in some cases severe lesions invisible in the roentgenogram have been detected by tomography. In the lumbar spine a central caries in the massive vertebrae of this region may be undemonstrable except by tomography. Intestinal gas shadows can also be differentiated. In latent, painless Pott's disease tomography may be the only possible means of diagnosis. In the sacral region, the tomogram will show clearly the sacral grooves and the continuity between the sacral canal and the anterior sacral grooves. Anteroposterior sections serve for a detailed analysis of the sacral alae.

EDITH SCHWARTZ MOORE.

Preoperative Roentgen Treatment in Breast Cancer Sigvard Kase. *Acta radiol. Stockh.* 947 8 53

Surgery still remains the choice method of treatment in carcinoma of the breast. The role of preoperative and postoperative radiation therapy has fluctuated with the years, and during the past few years the Memorial Hospital group has completely eliminated the preoperative course of irradiation.

The results with various forms of treatment seem to be a matter of statistics. Consequently, it is rather difficult to compare them. Despite this fact the author has attempted an analysis of 301 cases of breast carcinoma treated from 1931 to 1943.

All cases were histologically proved carcinoma and were either classified as stage I or II. In stage I the lesion was confined to the breast, and in stage II the axilla was involved either clinically or confirmed by surgery.

Five year survival statistics were compared with those of Pack and Livingston who used no irradiation. For both stages the survival rate was 49 per cent as against 40 per cent in the Pack and Livingston group. Harrington found that in the cases in which the Broder histological classification was stage III or IV the results were slightly better when irradiation supplemented the surgery.

An analysis of the frequency of local recurrence in the cicatrix and axilla 5 years following treatment revealed that it was less and was associated with a better 5 year survival rate.

On the basis of the studies made and a comparison of the results of various forms of therapy in breast carcinoma the author concludes that preoperative irradiation improves the 5 year survival.

MAURICE D. SACHS, M.D.

RADIUM

Cancer of the Cervix. Ira I. Kaplan and Rieva Roosh. *Am. J. Roentg.* 1947 57 659.

The authors report their method of treatment of 916 patients with cancer of the cervix over a period of 31 years at the Bellevue Hospital, New York, New York. Pathologically the lesions were of all types, the greatest number, however, being squamous cell (403) and the next largest group of lesions being of

the pleomorphic type (380). Irradiation was planned and outlined according to the extent, type and character of the local lesion. In most cases roentgen therapy preceded the local application of radium.

The roentgen therapy in all cases was 200 kilovolt high voltage rays, using 0.5 mm. or 1 mm. of copper or Thorium filter administered through four port fields, two anterior and two posterior giving 1,500 to 2,000 roentgens (measured in air) to each field. Following the completion of the roentgen therapy local radium therapy was administered with the use of a special ribbon colpostat. The usual total radium dose given was approximately 7,000 to 8,000 mgm.kt., 4500 mgm.kt. to the cervix and the balance to the uterus. Larger doses were given if the malignancy involved the cervical canal.

In 61 cases previous hysterectomy had been done. Late in 1938, with the publication of the League of Nations formula for grading cervical lesions, the cases were divided accordingly into four stages. Of the 916 patients treated 379 are alive 5 years or more and 60 are alive 10 years or more. Eight patients developed recurrence or metastases 7 or 8 years after treatment. In 34 cases classified as grade 4, 1 lived 8 years and 8 lived 4 years. In 331 cases treatment was not completed for various reasons. In 30 cases complicating conditions were encountered.

The authors believe that irradiation is the best method of treatment for cervical cancer in any stage but stage 1.

MISCELLANEOUS

Retention of Radioactive Iodine in Thyroid Carcinomas: Histopathologic and Radioautographic Studies. F. W. Foote, R. F. Hill, A. F. Hocker and L. D. Marinelli. *Am. J. Roentg.* 947 58 7.

The authors present 19 cases of thyroid carcinoma in which tissue sections and radioautographs were prepared and studied following the use of radioactive iodine by mouth. Several of the 19 patients received large therapeutic doses of the 8 day isotope (I^{131}) but a large majority received tracer doses ranging from 500 to 1,500 microcuries.

The technique consisted of administering tracer or therapeutic doses of radioactive iodine as sodium iodide in water solution by mouth 24 to 48 hours before surgery. Blocks of tissue about 3 to 3 mm. in thickness of both cancerous and noncancerous tissue are prepared and are then placed against the emulsion surface of a photographic plate or roentgen film. Areas of darkening on the photographic film map out the distribution pattern of the radioactive material in the sections to be examined. This pattern can be effectively studied by comparing it with the stained section by means of low power microscopy. Multiple sections were used. This served as a useful control and check over artefacts. Enlargement of the transparencies and corresponding magnification of the tissue sections revealed the histologic distribution of the radioactive material.

In the 19 selected cases included in this study there were 10 in which the presence of radioactive material was detectable by means of radioautograph ic determinations. Five of these were examples of benign metastasizing struma. The remaining 5 had the structure of follicular adenocarcinoma in some portion of the material studied.

From the foregoing it is clear that certain types of thyroid carcinoma do possess the ability to accumulate radioactive iodine. Furthermore it appears that structural type is an important determining factor. The pickup of the radioactive material is closely linked with structural qualities which include orderly cell arrangement in follicular pattern and the presence of colloidlike material. It is evident that these morphologic factors hold true for metastatic as well as for primary tumors in this study. In some of the cases which yielded positive radioautographs, there were portions of tumor that gave no evidence of ability to pick up the isotope.

On the basis of present findings and the estimation of the relative frequency of the various types of thyroid carcinomas approximately 15 per cent of thyroid cancers may be expected to accumulate radioactive iodine in some degree. The most favorable histopathologic type of thyroid cancer is the so-called benign metastasizing struma. Nearly the same statement can be made in regard to orderly follicular thyroid carcinoma. It is apparent that despite the rather close relationship between histopathological pattern and radiiodine pick-up a clean cut decision on the advisability of palliative or curative radiiodine therapy cannot be made on the basis of a limited biopsy since such a specimen may not reveal the more favorable histopathologic patterns that may be present.

FRANK L. HUSKEY M.D.

Carcinoma of the Skin: Influence of Dosage on the Success of Treatment. Clayton H. Hale and George W. Holmes. *Radiology* 1947 48 563.

The authors attempt to evaluate the effect that a given number of roentgens delivered to a carcinoma of the skin had upon the success or failure of the treatment. By comparing the results in a large group of lesions each of which had been given a different dosage it was hoped that an optimum dose might become apparent. This established optimum dose should be of value in determining the proper roentgen dose for skin cancer. Approximately 1,500 cases of carcinoma of the skin were reviewed in the order in which they appeared on the hospital records between the years of 1933 and 1944 inclusive.

A total of 1,035 lesions were irradiated with roentgen rays and 387 were treated surgically. Histological examination of 630 patients in the total group showed epidermoid carcinoma in 183 and basal cell carcinoma in 447. In the remaining cases treatment was given without histological confirmation because the clinical appearance was characteristic of carcinoma of the skin. The dose of radiation varied from 1,200 to 6,000 roentgens measured in air. Of the 893

lesions receiving a single massive treatment 54 per cent were irradiated with 200 kilovolts, 0.25 mm. of copper filter, 20 cm. skin target distance and half value layer 0.6 mm. of copper while the other 46 per cent were treated with 100 kilovolts the half value layer of which was 1 mm. of aluminum.

A tabulation of the results of the single massive dose method of irradiation in carcinoma of the skin over the range of the various doses used showed that 1,200 to 1,800 roentgens gave only an 81 per cent chance of destroying the lesion. The administration of 1,900 to 2,200 roentgens did not offer better than an 85 per cent chance, while the delivery of 2,400 roentgens might raise the expectancy to 91 per cent. A constructed curve showed that a lesion was as likely to be destroyed with a range of 2,500 to 2,800 roentgens as with the delivery of 4,000 roentgens. In the group of cases studied therefore, approximately 3,700 roentgens may be considered the optimum dose since it produced as satisfactory results as higher dosages and at the same time might be expected to leave the irradiated area in better condition.

A comparison of the results obtained with multiple treatments within the period of 1 week and of those obtained by the massive single dose method indicates that 3,200 to 3,600 roentgens must be delivered by the former method to produce the same results as were obtained by 1,900 to 2,200 roentgens by the latter method. Approximately 4,500 roentgens delivered in multiple treatments within 1 week produced essentially the same results as 2,700 roentgens given at one time. This dosage (4,500 roentgens) is suggested therefore as the optimum dose to be delivered to a carcinoma of the skin when the fractionated method (within 1 week) is to be used.

FRANK L. HUSKEY M.D.

The Treatment of Cancer Charles L. Martin and Carleton Wright. *J Am M Ass.* 1947 134 861.

Cancer of the exposed surfaces of the skin and cancer of the mouth are of unusual interest to physicians in the Southern states because of their high incidence in this area. The treatment of these lesions is described by the authors.

Epidermoid carcinomas of the skin and lip which measure less than 2 cm. in diameter and show little or no infiltration are treated with superficial roentgen therapy. The treatment factors are 85 kilovolts, 5 milliamperes, a 16 cm. skin target distance and a filter of 0.5 mm. of aluminum. An appreciable margin of normal skin around the edges of the lesion is included in the treatment area. Daily doses of 1,100 roentgens (measured in air) are given for 4 or 5 days, the total being 4,400 to 5,500 roentgens. Well elevated portions of the tumor are removed electrosurgically before roentgen therapy. The reaction is usually severe and healing occurs in 6 to 8 weeks. At the present time large lesions are treated with divided doses of deep therapy. The factors are 200 kilovolts, 20 to 25 milliamperes, a skin target distance of 30 cm. and filters varying from 0.5 mm. of copper and 1 mm. of aluminum to 0.8 mm. of

tin 0.35 mm. of copper and 1 mm. of aluminum. Ports up to 15 cm. on a side have been used successfully.

For squamous cell carcinoma, a daily dose of 300 roentgens (measured in air) are administered (skipping Sunday) until a total of 3,600 roentgens have been given. The sequence of events is similar to that observed with superficial technique. It is also desirable to remove polypoid lesions electro-surgically.

For lesions in the mouth, interstitial radium needle technique is used. The needles are made of platinum and have a wall thickness of 0.5 to 0.6 mm. and contain approximately 0.5 mgm. of radium per centimeter of active length. The needles found most useful have active lengths of 0.5, 1.5, and 4 cm. In order that the dosage may be easily estimated the needles are always left in place for exactly 7 days.

Elevated tumors are flattened electro-surgically before treatment. In flat tumors, needles are inserted into the base of the layer of growing tissue in patterns designed to deliver not less than 6,000 roentgens to all the tumor cells. Rounded tumors are treated by inserting the needles in two or more theoretic layers placed one above another. Radium needles are preferred to radon implants. The reactions are severe. Healing requires from 6 to 8 weeks or even longer depending on the size of the lesion.

Carcinoma of the skin of the forehead, temples, cheeks and neck, regardless of size or histological structure may be treated successfully with Ir radiation. Tumors measuring less than 3 cm. in diameter are treated by the superficial roentgenologic technique. The larger tumors, if they are fairly superficial, are treated with the Coutard technique, and with radium needles if there is much infiltration.

Tumors of the eyelids are treated with superficial roentgenologic technique. A gold-brass shield is slipped under the lids. The tumor area and a rim of normal tissue are all that is exposed to radiation. Malignant tumors of the inner canthus may be treated in this manner when they are superficial. Deep indurations which extend well down into the orbits are treated with a layer of weak radium needles with active lengths of 1.5 cm. plunged into the inner portion of the orbit. Cancers of the bulbar conjunctiva respond well to superficial roentgenologic techniques. Small superficial carcinomas on the nose may be irradiated with superficial roentgenologic technique. Larger lesions, particularly those which invade cartilage are removed by surgical diathermy.

Carcinoma of the ear presents a similar problem. Small lesions respond well to superficial roentgenologic technique. In large carcinomas, the overlying portion of the auricle is removed and radium needles are inserted into the remaining layer of the involved tissues on the side of the head. Invasion of the auditory canal is handled by stitching small radium needles into the wall of the passage.

Superficial carcinomas of the lip, measuring less than 3 cm. in diameter are treated with superficial roentgenologic technique. Large tumors and those showing deep induration respond extremely well to layer radium needle technique. In the treatment of carcinoma of the tongue lesions on the lateral border and tip can be reduced to flat layers for radon needle implantation by surgical diathermy. Masses in the center of the tongue are treated by placing needles, with 1.5 cm. active lengths, vertically into the tumors. Primary cancers in the floor of the mouth are treated by placing a vertical row of the smallest needles along the inner edge of the gum and augmenting them with a few 1.5 cm. needles placed transversely under the tumor. Carcinoma of mucosa of the cheek are usually flat and lend themselves to the layer radium needle technique. Primary lesions on the anterior part of the pillar and soft palate are always flat and are easily implanted.

After needle implantations are carried out the patterns are studied with roentgenograms of the involved area. Incorrectly placed needles are easily changed to correct technical errors. Metastatic cervical lymph nodes are treated by using a combination of the layer radium needle technique and the Coutard technique given simultaneously. The doses are large and the reactions rather severe.

The absolute three year cure rate in an unselected group of patients with advanced cancer of the face, lip, mouth, and cervical nodes, treated with irradiation, was found to be approximately 35 per cent. The relative 3 year cure rate in a group of unselected advanced cases was above 40 per cent.

FRANK L. HOWETT, M.D.

Radioactive Phosphorus as an External Therapeutic Agent in Basal Cell Carcinomas, Warts, and Hemangiomas. Bertram V. A. Low Beer. *J. Roentg.* 94:7 58-4.

Attempts have been made to use beta radiation in the treatment of skin diseases since its discovery. Beta radiation is particularly suitable for the treatment of superficial skin lesions because it penetrates only a few millimeters of skin. The effect of the rays is similar to that of roentgen rays or gamma rays. Early work with beta radiation was difficult because of the limited supply of material and because the available sources did not give off pure beta radiation.

The discovery of artificial radioactivity has made available substances which radiate beta particles only. Radioactive phosphorus (P_{32}) is one such substance. Absorption measurements have shown that approximately 48 per cent of the radiation from P_{32} is absorbed in the first millimeter of water or tissue and the absorption is practically exponential. The studies reported on were started in 1941 and after an interruption of 1 year were resumed in 1943. The best method found for the application of P_{32} was by means of a piece of blotting paper of known dimensions soaked in a measured quantity of radioactive sodium phosphate solution and dried. Office type blotting paper 0.4 mm. thick and weighing 11

mgm. per square centimeter was used. This was cut to size to cover the lesion with a safety margin of from 0.3 to 1.0 cm. according to the type of lesion. When prepared and dried the blotting paper is secured in place with adhesive tape and left there until the desired exposure in microcurie hours per square centimeter is obtained. Thirty-four microcurie hours per square centimeter were determined as the threshold erythema dose.

During the period from March 1943 to October, 1945 301 skin lesions were treated by the external local application of P_{32} these were included in this report. Basal cell carcinoma (52) hyperkeratosis (36) verrucose hands (132) plantar warts (50) subungual warts (16) and hemangiomas (17) were treated. During the early stages of these studies the dosage of the radioactive phosphorus varied considerably among the cases treated. The reactions of these various doses were carefully observed and recorded and a pattern of dosage has now been established.

The purpose of this report is to demonstrate that radioactive phosphorus a pure beta radiator can be used satisfactorily in the treatment of superficial skin diseases.

S. A. PATTERSON M.D.

The Deposition of Radioactive Metals in Bone as a Potential Health Hazard Joseph G. Hamilton
D. Harold Copp and Dorothy J. Axelrod *Am J Roentg* 1947 58:10

The radioactive elements involved in nuclear fission present danger to those working in production plants and laboratories handling this material. With the probability of a nuclear chain reaction pile the amounts of radioactive materials involved would be many million times greater than anything encountered in the radium industry. Fortunately many of these radioactive products produced in this way have short half lives so that radioactive decay quickly

reduces their concentration. Certain isotopes however including those of strontium (Sr), yttrium (Y), cerium (Ce) and plutonium (Pu.) have such long lives that the contamination of the personnel handling them can be a serious problem because these elements are rapidly fixed in the skeleton and are eliminated at a very slow rate. The sensitive cells of the bone and the bone marrow are therefore exposed to toxic radiation. Studies were done on rats to investigate the factors concerned in the absorption and deposition of these elements, their chronic elimination and a possible mechanism for reducing the toxicity of the plutonium which is deposited in bone.

The first element studied was strontium. This was the only element in the group which was absorbed to any significant extent from the intestinal tract. It was found that young rats fed orally on a low calcium diet absorbed 15 times as much of this element as did adult rats on a high calcium diet and 4 times as much when the strontium was injected intraperitoneally. It was therefore felt that exposure to radiostrontium or radium should be restricted to adults and that a high level of calcium intake should be maintained.

In contrast, there appeared to be no significant difference in the behavior of plutonium, yttrium and cerium when these same two groups of rats were compared. Further studies showed that the retention of strontium was greatly reduced in phosphorus deficient animals. There was no significant effect observed with regard to the retention of plutonium, yttrium, or cerium. It was shown by radio autographs that strontium appeared to follow the path of calcium metabolism and was deposited only in the bone salt while the 3 other substances were laid down in the uncalcified organic matrix of the bone and appeared to be unrelated to calcium in behavior.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Myasthenia Gravis and Tumors of the Thymus; a Clinical and Anatomicopathologic Study (Miastenia gravis y tumores del timo estudio clinico y anatomicopatológico) Aquiles Salvador Lentino. *Sem. med., B. Air* 1947 54 533

This treatise demonstrates the clinical and anatomicopathologic relationship of myasthenia gravis to certain abnormalities of the thymus. These are grouped under 3 headings: (1) a persistent thymus or subinvolution of the thymus; (2) hyperplasia of the thymus which consists of a quantitative as well as a qualitative increase in elements of the thymus; and (3) neoplasms or thymic tumors. The last are encapsulated and show epithelial hyperplasia. It is difficult to differentiate many cases from a simple increase in substance and adenoma formation. Histologically the tumors are thymocytomas, thymopitheliomas, or mixed tumors.

A detailed analysis of 5 cases is presented in which biopsy or autopsy section was studied. The diagnosis in 1 case was thymopithelioma, in another it was adenoma, and in the remaining 3 cases it was hyperplasia with subinvolution.

It is concluded that there is a true relationship between myasthenia gravis and an altered thymus.

STEPHEN A. ZIEGLER, M.D.

Management of Respiratory Complications of Poliomyelitis. Thomas C. Galloway. *Arch. Otolaryngol.* 1947 46 15.

The author stated that the problem of severe bulbar poliomyelitis is largely one of secretional obstruction of the respiratory tract with secondary anoxia. In other words, anoxia due to accumulated secretion is a most important factor in this condition.

Respiratory complications are of 3 types: (1) those due to spinal paralysis involving the diaphragm or intercostal muscles, or both; (2) those due to bulbar paralysis involving the mechanism of deglutition; and (3) those due to disturbances of the respiratory center.

Complications of the first type usually respond well to the use of the respirator. In patients with bulbar paralysis, the respirator should be used with caution; the airway should be cleared of secretion or by passes provided by tracheotomy.

The indications for tracheotomy are outlined as follows: (1) fluid in the upper airway with increasing signs of anoxia, in spite of the administration of oxygen, postural drainage, and aspiration (restlessness, dyspnea, cyanosis, disorientation and mental depression are important determinants); (2) unconsciousness or marked restlessness in a patient not previously treated and not responding to other

treatment in a few minutes; (3) marked restlessness or stupor in a patient in a respirator even if he apparently has a spinal type of poliomyelitis; (4) fluid accumulation not otherwise easily and certainly taken care of in a patient requiring the respirator; (5) rapidly progressive bulbar symptoms; (6) bilateral paralysis or spasm of the vocal cords; (7) markedly increasing signs of vasomotor failure not explained as due to a cause other than anoxia, and (8) untrained or inefficient attendants, inadequate equipment, or poor co-operation of the patient with doubt that the airway will be kept free of any secretion.

If a patient under observation loses consciousness, it probably means that intervention has been delayed too long.

ROBERT TURELL, M.D.

Pilonidal (Sacrococcygeal) Cyst and Sinus. Robert Turell. *N. York State J. M.* 1947 47 977

The author describes certain facts about pilonidal disease which became evident during World War II, and he indicates the trends of choice of surgical procedures.

It was again stated that there exists no unanimity of opinion as to the embryologic origin of this lesion. While it is agreed that pilonidal cyst or sinus is congenital in origin and that it arises from the ectoderm, it has not yet been definitely determined whether skin or neural tissue is the source of origin. Also, there is a decided lack of agreement concerning surgical therapy as attested to by the numerous new procedures and modifications of old procedures. In many instances the good results claimed by the authors of these procedures are not always obtained by surgeons other than the originators.

During World War II pilonidal disease became a major surgical problem because of its frequent occurrence in militarized personnel. It became apparent that trauma plays an important role in the activation of this lesion. The author also observed that hyperhidrosis and lack of ideal personal hygiene imposed by training and/or battle conditions are as important factors in the initiation of infection in the pilonidal cyst or sinus. Operative specimens removed at initial operations yielded hemolytic and non-hemolytic staphylococci and streptococci members of the colon bacillus group of organisms were notoriously absent in these surgical specimens. Similar findings were obtained when the subcutaneous tissue juices of the buttocks, as far as 3 cm. from the line of excision of pilonidal cysts, were studied bacteriologically.

Abscesses are operated upon as early as practicable. Through a generous incision the pus, necrotic material and, frequently, tufts of hair are evacuated and the cavity is irrigated with normal saline solution. The roof of the abscess cavity is then removed, hemostasis is secured by gentle pressure, and the

cavity is packed lightly with gauze which has previously been soaked in a solution of penicillin. In spite of excision of a large amount of overlying skin, as is frequently necessary in the case of large abscesses, the wound is usually well healed in about 3 weeks and the entire convalescence is extremely smooth. By comparison with the method of crucial incision and drainage only the wide unroofing of the abscess cavity is a far superior procedure. Recurrences in 3 to 6 months after operation have been absent.

Cysts or sinuses in civilian pre-war practice were popularly excised en bloc and packed. This operation entails a prolonged period of healing, a factor that made this operation undesirable in military war practice. To restore soldiers to duty as early as possible, various closed methods or techniques were utilized. In the author's experience, the musculofascial flap operation described by Shute, Smith, Levine, and Burch (or that of Holman) with the addition of the principle of delayed closure to the middle and upper portions of the wound, was found to be a rational and effective procedure and one that can be performed with ease after some experience with this technique has been secured. The operation is applicable to very large uninfected or previously drained cysts with or without multiple sinuses.

Recurrences may also be treated by this technique. Other forms of treatment for recurrent pilonidal disease are irradiation, injection of the sinuses with sclerosing solutions and penicillin and excision en bloc followed by immediate skin grafting, utilizing intermediate or thick split thickness skin grafts. The author's experience supports the belief that the freshly exposed area is a good base upon which to place a skin graft.

Chemotherapy, sulfonamides, or antibiotics, have a definite place as an adjunct to surgery and should be administered before and after operation, especially in the complicated cases. The author observed that penicillin given early in large doses is effective in preventing abscess formation in a certain number of cases of cellulitis of the pilonidal area which in the past, usually terminated in frank suppuration.

The choice of the form of anesthesia is of importance. Local infiltration anesthesia appears to produce a higher incidence of complications (infection) than regional or general anesthesia and thus is responsible for a longer period of hospitalization.

Injectional Treatment of Internal Hemorrhoids.

Robert Turell. *Am J M Sc* 1947 513 359.

The present article is based on a study of 100 private patients who suffered from uncomplicated small to medium-sized internal bleeding hemorrhoids with or without spontaneously reducible prolapse. Private cases were chosen for this investigation because all the details of examination, treatment, and follow up were carried out by the author in contrast to clinic patients who are not always treated and supervised by the same surgeon.

The preinjection studies included a competent general and regional digital and instrumental ex-

amination and a minimum of laboratory tests consisting of urinalysis, hemoglobin estimation and a serologic test for syphilis. A sedimentation test of the blood and a roentgenray study of the colon by means of a double contrast barium enema were made only when specially indicated.

The injectional technique is described in detail. The sclerosing agent utilized in most cases was a 5 per cent solution of quinine and urea hydrochloride 5 to 10 per cent of phenol in pure almond oil was used in a small number of patients. The first injections were made submucosally above the anorectal ring about the pedicle of each hemorrhoid. After all the hemorrhoids had thus been treated, subsequent injections were made into the hemorrhoidal masses at a lower level. Occasionally additional submucous injections were made between treated hemorrhoids in order to correct mild mucosal prolapse. Usually the injections were made biweekly. On occasions all high submucous injections were made in one sitting and subsequent interstitial injections were completed at biweekly or triweekly intervals. A total series of from 6 to 12 injections was usually required.

Postinjectional care consisted in instructing the patients to avoid straining and how to avoid constipation which may be the cause of defecatory straining. The patients were asked to feel for anal protrusions and were told how to reduce such protrusions digitally and to report such occurrences promptly.

The main clinical purpose of this treatment is to stop bleeding and to correct the associated descensus of the rectal mucosa. This was accomplished in every instance. About 65 per cent of the patients remained symptom free during a follow up period of observation ranging from 30 months to 3 years. Reinjection was required in over 30 per cent of the patients because of recurrence of hemorrhoids causing bleeding 9 months or more following the conclusion of the original course of treatment.

Seven cases of inconsequential superficial slough at the site of injection were observed in this series of patients.

Surgical excision in a large number of cases was compared and contrasted with injectional treatment. As a result of this study operation is usually not applied to the treatment of small or medium-sized internal hemorrhoids, but is reserved for the treatment of large internal or interno-external (mixed) hemorrhoids and hemorrhoids that are associated with or complicated by anorectal lesions that require surgical excision.

ROBERT TURELL, M.D.

The Operative Treatment of Decubitus Ulcer. Edmund J. Croce and Charles H. C. Beaken. *England J M* 1947 537 141.

The management of decubitus ulcers in 130 paraplegic patients at Halloran General Hospital, Willowbrook, Staten Island, New York, over a 15 month period is reported. Operative treatment is indicated because it boosts morale, terminates loss of tissue

protein and increases appetite, strength, weight and general well being. The objects of treatment are to obtain early complete closure and to obtain a permanently stable closure. Split thickness grafts are frequently used as an early expedient in patients not ready for more extensive surgery but should be replaced by full thickness grafts at a later date in order to obtain a stable closure. In the early phase the decubitus ulcer exhibits extending necrosis, and the exudation of body fluids is profuse. Treatment at this stage must consist of restoration of protein anabolism, conservative débridement of necrotic tissue, chemotherapy and transfusions. Later when necrosis ceases, healthy granulations appear and cellulitis subsides, the wound should be temporarily closed by split thickness grafts.

Though bacteriological studies were carried out in preparing for coverage with extensive flaps, more reliance was placed on the appearance of the wound than on the culture. An ulcer was considered ready for this procedure when cellulitis subsided, healthy granulations presented, nonviable tissue had separated, exudation had practically ceased and the wound margins presented proliferating epithelium. Most patients required no anesthesia since most ulcers were below the sensory level. Operative technique required sharp dissection, excision of all scarred tissue, fine silk hemostats, flaps sufficiently extensive to allow closure without tension, thorough irrigation of the wound with saline, dusting with plasma penicillin powder and the maintenance of pressure dressings.

The sacral ulcers were closed by sliding flaps upward from the buttocks and medially from the lumbar regions, depending on the size and shape of the defect. Trochanteric ulcers presented a more difficult problem due to the tightness of the skin over the hip, the mobility of the area, and the frequent occurrence of false burrs. These were usually closed by linear suture, single sliding flaps, or double sliding flaps. It is believed that immobilization in a padded spica with the hip abducted will improve results.

Paraplegic patients frequently developed redness and swelling over the ischial regions and if these areas were mistaken for abscesses and incised, ulcers then developed which communicated with a chronically infected ischial bursa. These are best treated by excision and linear closure. Calcaneal ulcers were treated by nonoperative methods.

ROBERT ALATO TENERY, M.D.

Anomalies of the Extremities and Their Genetic Problem (Le anomalie della estremità ed il loro problema genetico) G. LUG. *Riv Ital Sci.*, 946, 29-93.

The 3 cases of anomaly of the extremities reported by the author represent 3 different processes, one of addition and one of subtraction. One is a case of polydactylism and the other a case of perodactylism made more complex by the absence of 3 metacarpal bones and abnormal structure of the only finger present which made it impossible to identify it as a finger.

In the discussion of the etiology the author states that external causes, e.g., diseases of the uterus and adnexa, hydramnios, small uterus, are not factors, but in polydactylism internal causes are very important. The problem of teratogenesis is not explained by Rabe's article on polydactylia, schizodactylia, diplocheiria and dipodactylia, neither is the problem elucidated by the atavistic theory of Foltz, Bardeleben, Albrecht, and Darest.

The author adheres to the teachings of Spemann (1918) namely that embryonal development depends on successive organizing actions. These actions are of the first and second order and include those which have to do with the development of single organs. Any abnormal development due to internal causes must follow abnormal behavior of the organizers themselves. These organizing factors go beyond the cellular limits and may transmit themselves by contact. Studies undertaken to ascertain the nature of these organizing factors have focused the attention of everyone on the sterols.

According to Witsche, all teratological events are due to an alteration in the metabolism of the sterols. If this hierarchy of inductive actions is admitted, then the development of an extremity becomes a secondary process, and in our first case—the case of addition—we have a morphological hyperproduction of the normal parts of the extremity while in the second—the case of subtraction—a more or less altered structure follows an evolution influenced by regional characteristics. It is hard to determine the "primum movens" of this teratological deviation. It is important to add that these sterols, which constitute the organizing substances, are influenced by male and female hormones. JOSEPH M. A. PATE, M.D.

DUCTLESS GLANDS

Augmentation of Thyrotropic Potency by Goitrogens. Alexander Albert, Rufon W. Rawson, Priscilla Merrill, Beatrice Lennon, and Charlotte B. Riddell. *Endocrinology* 1947 40 303.

The authors observed in control experiments that the exposure of known amounts of active thyrotropic (TSH) extract to a variety of reducing agents resulted in enhancement of the thyroid stimulating activity of the extract, the augmenting effect by goitrogenic agents being proportionately much greater than that induced by nongoitrogenic compounds. Furthermore, they found that the augmenting action was not dependent on the continued presence of the augmenting agent during the bio-assay procedure.

As is well known, thyroid weight and mean acinar cell height are directly and thyroidal iodine concentration inversely, proportional to thyrotropic activity within certain limits of dosage. By virtue of its greater sensitivity and measurability, calculations were made entirely from the values of thyroidal weights.

That reduction per se did not completely explain the results obtained was evident from the observa-

tion that ascorbic acid a strong reducing agent destroyed TSH activity instead of enhancing it.

DAVID H. LYNN M.D.

The Effect of Goitrogenic and Other Reducing Agents on Inactivated Thyrotropic Hormone Extract. Alexander Albert Rulon W. Rawson Patricia Merrill, Beatrice Lennon, and Charlotte B. Riddell *Endocrinology* 1947 40 199.

It has been shown previously that treatment of a thyroid stimulating hormone (TSH) extract with elementary iodine resulted in precipitation of most of the proteins of the extract the precipitate having lost from 95 to 100 per cent of its original thyrotropic activity. Removal of 60 per cent of the iodine from this precipitate by trituration in an excess of acetone restored the original thyrotropic potency to the protein residue. Several goitrogenic reducing compounds were similarly found capable of reducing the loosely bound iodine and reactivating to varying degrees of original thyrotropic activity the hormonal iodinated TSH extract precipitate. Identical effects were accomplished with nongoitrogenic reducing agents although when sodium hydroxide was used, hormonal activity was not restored.

The results of this study concerning the effects of reducing agents, including control experiments showed that the reactivation of the iodinated TSH extract was due to some interaction between the reducing agents and the iodinated precipitate and not to the reducing agents themselves or to their interaction with any one of the other two compounds (TSH and iodine) of the system.

DAVID H. LYNN M.D.

The Thyroxine-like Action of Elemental Iodine in the Rat and Chick Samuel Droskin *Endocrinology* 1947 40 334

Experiments designed to determine whether iodine has an action similar to that of thyroxine were based on four known actions of thyroid gland powder and thyroxine (1) the ability to restore and maintain growth after thyroidectomy (2) the ability to restore the weight of the adrenal gland of thyroidectomized rats to normal, (3) the ability in normal rats, to cause involution of the thyroid gland epithelium and to decrease the weight of the gland (4) the ability to prevent hypertrophy of the epithelium of the thyroid gland and to prevent increase in weight of the gland due to the administration of thiouracil or sulfadiazine to normal rats. The iodine was tried in two forms as elemental iodine (I₂) and as reduced iodine (I⁻) in the form of the iodide (NaI). The effectiveness of oral and parenteral modes of administration was also determined.

The results of the experiments were as follows (1) when a solution containing elemental iodine was injected subcutaneously in young female thyroidectomized rats bone growth was reinitiated and body length increased. An equivalent dosage of iodide gave only minimal growth stimulating effects (2) elemental iodine administered subcutaneously

prevented the loss of weight of the adrenal gland which occurred in thyroidectomized animals iodide did not prevent it (3) the elemental iodine given subcutaneously to normal young female rats caused a marked decrease in the height of the cells of the thyroid epithelium and an accompanying decrease of weight of the gland equivalent injections of iodide did not alter the weight of the gland and lowered the cell height only slightly (4) the goitrogenic effect in thiouracil in chicks and rats and of sulfadiazine in rats was greatly or completely inhibited by the subcutaneous administration of a solution containing elemental iodine. Iodide in equivalent subcutaneous dosage did not alter the histological character of the gland but did reduce its weight somewhat. When the elemental iodine solution was given orally it had no more effect on thyroid weight and structure than did the iodide given orally.

The experiments demonstrated clearly that elemental iodine administered subcutaneously to rats and chicks produced effects similar to those of thyroxine whereas iodide administration produced only minimal thyroxine-like activity. The results emphasize a fact to which other investigators have called attention, namely that oxidative mechanisms are important in the formation of thyroxine in the body. Such mechanisms apparently liberate elemental iodine which can then be incorporated into the molecule of an organic compound. Although the existence of an iodase in the thyroid gland having ability to oxidize iodide to elemental iodine has been postulated no such enzyme has been definitely isolated. BENJAMIN F. LOUNSBURY M.D.

Contribution to the Diagnosis and Treatment of Virilism. Hans Ludwig Kottmeier *Acta obst. gynec. scand* 1947 27 131

Virilism in the menopause is usually physiologic although its pathogenesis is still obscure. Virilism in fertile women is frequently a pathological symptom but one must distinguish between virilism and hirsutism because the latter may be hereditary. In masculinizing ovarian tumors the following symptoms may coexist: amenorrhea, atrophy of the breasts, masculine mental and physical characteristics, low pitched voice, excessive hair on the face, thinning of the hair of the scalp, pigmentation and pustulation of the skin and hypertrophy of the clitoris. These same symptoms may also accompany tumors of the adrenal cortex. Cushing's syndrome may present these same symptoms plus a painful type of obesity, dry skin, striae, moon face, demineralization of the skeleton, hypertension, hyperglycemia, glycosuria and erythema. This syndrome has been attributed to "pituitary basophilism" but the pathological etiology is becoming increasingly obscure.

The author believes that the term arrhenoblastoma should be reserved for those ovarian tumors which are accompanied by masculinization and he agrees with R. Meyer that masculinization symptoms are more pronounced in the least differentiated tumors.

INTERNATIONAL ABSTRACTS OF SURGERY

The author prefers the term arrhenoma rather than arrhenoblastoma because it does not refer to the genesis of the neoplasm, which is still obscure.

Three cases of arrhenoma are presented from the Radiumhemmet, Stockholm Sweden. Two of these were improved after oophorectomy the third case terminated fatally because of bone metastases from a local recurrence of the tumor. In view of this case the author believes radiotherapy should be considered after surgery even though there is no pathological evidence of malignancy.

Two cases of Cushing's syndrome from the same clinic are presented. In both cases the signs and symptoms were pronounced and radiotherapy of the hypophysis was given without exploration of the adrenals since this procedure is considered dangerous in patients with Cushing's syndrome. Both patients showed marked improvement after irradiation and the author believes that this is further evidence that the hypophysis is involved in this condition.

ROBERT MAYO TERRY, M.D.

EXPERIMENTAL SURGERY

Curare and Shock: The Production of Hemorrhage Into the Upper Intestine of the Dog with Large Doses of Curare. Frank Cole Ivan D Baronovsky and Owen H. Wangersteen. *Surgery* 947: 182.

The objects of this experimental study on 18 dogs were the determination of the mechanism of the production of intestinal congestion and bleeding, the pathologic changes developed by large doses of curare, and the effects of large amounts of curare on the blood pressure.

Intocostin, a preparation of curare, was used in doses ranging from 0.035 to 1.335 c.c. of Intocostin per pound of body weight and were always given as 1 injection and rapidly.

The results suggest the necessity for close scrutiny of the doses used in man. It has been shown that the minimal lethal dose of Intocostin in the dog is 0.065 c.c. per pound of body weight. If artificial respiration is used pathologic changes appear with doses of 0.650 c.c. per pound. Dogs can be killed by doses of 1.3 c.c. per pound even when artificial respiration is maintained. In man 0.035 c.c. of Intocostin per pound is commonly injected, and as much as 0.20 c.c. Doses sufficient to produce muscular relaxation and respiratory depression appear to be nearly alike in proportion to body weight in man and in the dog. The dog appears able to withstand anoxia better than man.

It was found that when large doses of curare (from 0.718 to 1.240 c.c.) were administered intravenously in single injections to dogs kept alive by artificial respiration for from 2 to 5 hours, congestion and a fatal fall in the arterial blood pressure were produced in shock. Intestinal bleeding does not occur when the systolic blood pressure is maintained at a level between 80 and 90 mm. Hg.

It has been known that intestinal hyperemia, mucosal hemorrhages, and duodenal and jejunal ulcerations were found in late shock along with congestion of the liver, spleen and kidneys. The authors conclude that the intestinal pathology found on the basis of the shock produced.

These experiments show that curare does not stimulate gastric secretion nor does it produce gross congestion of the mucosa of the small intestine when applied topically. Vasoconstricting drugs such as epinephrine and ephedrine will prevent the severe depression of the arterial blood pressure subsequent to the intravenous injection of large amounts of curare. The failure of transfusions of whole blood to maintain the blood pressure is attributed to the inhibition of the vasomotor center and ganglia caused by curare. The potential "lake" formed by the dilation of the visceral vessels and these organs cannot be filled fast enough, and little, if any, blood returns to the heart. The heart itself is affected by large doses of curare and this occurrence in itself will prevent a blood pressure rise after transfusion.

When shock is averted, intestinal hemorrhage is not seen. Shock is therefore, the most likely cause of the intestinal hemorrhage resulting from the intravenous injection of large amounts of curare.

JOHN H. MONARD, M.D.

Studies of Thermal Injury: An Exploration of the Causality Producing Attributes of Conflagrations; Local and Systemic Effects of General Cutaneous Exposure to Excessive Chromatophore (A1r) and Circumradiant Heat of Varying Duration and Intensity. A. R. Moeht, F. C. Henriques, Jr., F. R. Dutra, and J. R. Weisberg. *Arch. Path., Chic.* 947 43 466.

In a series of pilot experiments, in which guinea pigs were burned in a fireproof chamber with and without adequate ventilation the changes that occurred in the oxygen carbon dioxide and carbon monoxide contents were observed, the temperature of the air was measured and the results of exposing animals to such conflagrations were observed. The most important information gained from these pilot experiments was that large animals, exposed to such conflagrations may receive injuries that are almost immediately fatal, and that the fatality is not necessarily contributed to by asphyxia, carbon monoxide poisoning, or inhalation of flames or fumes. Almost immediate death may result from systemic disturbances caused by the heat flowing through the surface of the body.

Source temperatures of about 90 degrees centigrade could be tolerated for 45 minutes without burning, whereas, at 100 degrees burning occurred in 15 minutes, and at 120 degrees, 30 seconds was the longest exposure that could be tolerated without irreversible cutaneous injury.

Although the temperature of the skin was considerably lower than that of the heat source in the

hot air exposures, the relationships of time and tissue temperature that were responsible for cutaneous burning in these experiments were essentially the same as those that prevailed in the experiments with hot water exposures. At relatively low temperatures of heated air (under 120 degrees C) man is less susceptible to injury than the pig because of his ability to sweat. It is doubtful, however that sweating provides a significant degree of protection at temperatures over 120 degrees centigrade because, at such levels, the rate at which heat is transferred to the skin is much more rapid than the rate at which it can be dissipated by vaporization of sweat. The relationships of source temperature to production of injury established by the experiments, apply only to unprotected skin and are not valid for exposures in which hair or clothing is interposed between the skin and the source of heat.

Excessive circumambient and circumradiant heat, though applied for periods as brief as 30 seconds is capable of precipitating in pigs, dogs, and goats physiologic disturbances of sufficient severity to cause death within a few minutes. The severity of the physiologic disturbances that result when animals are exposed to excessive heat is often disproportionate to that of the cutaneous burning. Rapidly fatal systemic hyperthermia may result from long duration exposures at temperatures insufficient to cause cutaneous burning. Higher intensity exposures may cause extensive and severe cutaneous burning and yet be of too short duration to cause a significant rise in body temperature.

The severity of the immediate physiologic disturbances resulting from exposure to excessive heat appears to bear a direct relationship to the extent to which the body temperature is increased. Exposures that failed to cause the rectal temperature to rise above 42 degrees centigrade rarely resulted in rapidly fatal circulatory failure those that caused it to rise as high as 44 degrees invariably did. In the pig such a rise in body temperature may occur within a few minutes after cutaneous exposure to excessive heat and does not persist for more than a few hours after termination of the exposure. In animals that died within a few minutes after being exposed to excessively high environmental temperatures the temperature of the heart's blood was consistently higher than that recorded by a rectal thermometer the shorter the interval between the onset of the exposure and the death the greater was the difference between the two temperatures.

Apart from the cutaneous lesions the pathologic changes observed at autopsy are not pathognomonic of thermal injury. Subendocardial ecchymoses were the most constant abnormalities found in animals that died during or soon after exposure. Other post mortem findings included stasis of blood in the peripheral vascular bed moderate dilatation of the right auricle, and persistent fluidity of the blood. In the case of extensively burned animals there was intra vascular hemolysis. Blood smears showed fragmentation of erythrocytes. In animals that survived

severe thermal exposures as long as 24 hours the urine was found to contain large amounts of hemoglobin, and degenerative changes were frequently identified in the cells of the renal tubules the adrenal cortex, and the liver
SAMUEL KAHN M.D.

The Predictability and the Significance of Thermally Induced Rate Processes Leading to Irreversible Epidermal Injury F C Henriques, Jr
Arch. Path. Chlc. 1947 43 489.

Of all the physical and chemical processes known to date, thermally induced epidermal injury is probably due primarily to thermal changes of those proteins and enzymes whose rate of alteration corresponds to an activation energy of at least 150 kilocalories per mol and an entropy change of about 395 units. This is consistent with the known existence of a reversible phase of latent epidermal injury
SAMUEL KAHN M.D.

The Effect of Powdered Whole Blood Cells and Plasma on the Healing of Wounds (Sull'azione delle polveri di sangue, di globuli rossi e di plasma nei processi di guarigione delle ferite) U Brancato
Rass. internaz. clin. ter. 1947 27 87

Uniform wounds were studied in several dogs, and the effect of desiccated preparations of whole blood cells and plasma, locally applied, was estimated by tracings on sterile glass slides. Wide variations in the rate of healing were found in the controls as well as in the treated wounds. No advantage was observed as a result of using materials prepared in the author's laboratory. Powdered red cells furnished by the Istituto Sieroterapico di Milan on the other hand appeared to hasten healing.

EDITH B FARNSWORTH M.D.

Fascia Lata Regeneration Animal Experimentation J C. Poolee
Surgery 1947 21 800.

This study was undertaken to obtain pertinent data relative to fascia lata regeneration. With sterile technique throughout and fine silk for hemostasis as well as for the purpose of identification during succeeding operations 22 experiments were performed on the fascia lata of 3 dogs at 3 different periods. When both extremities were opened during the same operation it was considered 2 separate experiments. In most of the procedures a small segment of fascia lata was excised and the superficial wound was closed with silk. In some 2 defects were fashioned to leave an intervening strip of normal fascia lata. In 3 additional experiments, the segments were rostited 90 degrees after being cut, one being turned over as well to interchange the inner and outer surfaces. Subsequently the sites were reopened after from 14 to 97 days and grossly inspected, and a block of tissue consisting of the regenerating area as well as a rim of adjacent normal fascia was removed for microscopic study.

Normally fascia lata possesses an inner and outer transverse and a middle longitudinal layer. Once a defect was produced the regeneration was charac

teristic in all save 1 instance. The middle layer atrophied and disappeared while the inner and outer layers regenerated by extension directly from their respective layers in the adjacent normal fascia lata together with their sheaths and blood vessels. Furthermore the transverse layers underwent hypertrophy and hyperplasia if they were required to take over the full compensatory pull of the middle layer when the severed segment of fascia lata was rotated 90 degrees. This confirms the early studies of Kleinachmidt.

The author concluded from these experiments that in a medium sized defect the average rate of regeneration is as follows:

At the end of 2 weeks the regenerated fascia lata is only a thin veil. It becomes more dense rapidly. At 3 weeks it is a well defined membrane. At 1 month it is half as thick as normal fascia lata, and at 2 months it is grossly and microscopically as thick as the normal fascia. In a very large defect the process of regeneration may be slower but in a smaller defect it may be so rapid that in 1 month the regenerated tissue will become as thick as the normal fascia lata.

D. VAN H. LYNN, M.D.

Fascia Lata Regeneration. Final Report. J. C. Forbue. *Surgery* 947 89

A clinical study of the regeneration of fascia lata in 5 patients from whom fascia lata had been removed for the reoperative repair of hernias is presented. This publication is a supplementary report to a previous article on fascia lata regeneration by the author.

Microscopic study of fasciae from patients who had been reoperated upon revealed that the healed fascial tissue was not scar tissue but a structure of well organized layers of certain parts of the normal fascia lata, such layers having their own sheaths, and

these sheaths were combined in a common sheath, each sheath having its own minute blood vessels.

Normal fascia lata is comprised of 3 layers, namely an inner transverse layer, an outer transverse layer, and a strong middle longitudinal layer. Each layer is enclosed in its own fine sheath and all 3 layers are encased in a denser common sheath. Evidence is presented that it was the inner and outer transverse layers that were regenerated. These layers were in continuity with and extended directly from their corresponding layers in the normal fascia lata which extended across the defect regardless of its size.

The conclusions deduced are that it is not necessary to suture layers of fascia across the defect from which a transplant has been taken, or to make an effort to repair the defect to prevent herniation, a herniation will be prevented by the newly formed fascia. The more active the individual, the more dense and better developed will be the regenerated fascia, and the regenerated fascia from 6 months to 1 year of age will be of sufficient density and tensile strength to be used successfully in surgical procedures in which ordinarily normal fascia is desired but lacking.

This study does not appear to substantiate the work of Gratz, to the effect that fascia will develop anywhere in the body from muscle where fascia is needed. In every instance in this work it was shown that the regenerated fascial layers are direct extensions across the defect of the corresponding layers of adjacent normal fascia lata. The thickness and density of the inner layer of the regenerated fascia in comparison to these qualities of the outer layer suggests the importance of the proximity of muscle to the success of fascial regeneration. This has been disclosed by the loose attachment to the muscle by trabeculations as in normal fascia lata.

THE USE OF ISOTOPES IN SURGICAL RESEARCH

FRANCIS D. MOORE, M.D., F.A.C.S., Boston, Massachusetts

THE rapidly widening horizon of medical research with radioactive and stable isotopes of the common biologically important elements has long since come to include the sphere of surgery. Indeed surgeons were among the earliest of the clinical groups to employ these useful tools in the study of physiologic and biologic problems.

Such materials are now becoming widely available for surgical research in this country and in foreign countries. It is especially appropriate to review in brief some of the salient points of the history of this type of work, its biologic potentialities and a few of the practical problems facing the investigator. It is with this purpose in mind that the material presented herewith has been gathered together.

It is important to acknowledge at the outset that the author is not a physicist; he has had little contact with the recent physical marvels from betatron to Bikini. The thoughts expressed herein are based on a limited experience over a 7 year period with radioactive isotopes of bromine, chlorine, iodine, sodium, potassium, iron, phosphorus and with deuterium. Although we must deny that research with isotopes is a field in itself any more than research with a colorimeter constitutes a field in itself, there are certain pertinent considerations which may help the investigator. It is our present purpose to outline some of

these—though they may seem elementary to some and controversial to others. The fundamental physics of the materials and devices herein discussed are set forth in several standard works and no effort to review this material will be made in this paper (12, 21, 31, 36, 40, 43, 44, 56, 68).

The period of cyclotron production of radioactive isotopes for biologic research (1939-1945) saw the initial exploration of this area by a small number of investigators. On the physical side, techniques of production, separation, and measurement of radioactive isotopes of most of the biologically important elements were developed. Biologically, the *in vivo* distribution of these substances was studied, permeability and rates of exchange were observed where possible, and in certain instances the incorporation of active atoms into the complex organic materials was investigated.

Many lessons about investigative technique were learned. Though the use of radioactive materials involves many physical problems and though the physicists were responsible for the discovery, production, and separation of the isotopes and their measurement, the medical application of these materials was soon found to be a biological or biochemical problem at heart—with physics only as hand maiden.

If one is to study bone physiology with Ca^{45} , it is important to know what in general is meant by a beta ray energy of 0.25 Mev, as this concerns the counter window thickness

From the Department of Surgery, Harvard Medical School and the Surgical Service, Massachusetts General Hospital.

SURGERY GYNECOLOGY AND OBSTETRICS

or the preparation of samples with a constant coefficient of self absorption it is wise to be aware of the relation of half life to working usefulness of the isotope mixture. If these considerations be physics then they must be accepted as such and learned. But the mate kinetics of the nuclear reaction involved the gain or loss of a neutron the factors involved in capture cross-section and similar matters are physical and technical problems whose details need not concern the medical investigator. In the sense of time spent, the less he knows about them the better. To use a photoelectric colorimeter one need not study the physical basis of light transmission, absorption and optical systems, as long as the essential limiting factors are understood and given their due respect.

This was the first lesson learned in the cyclotron period though the application of isotopes to medical and biological research is in effect a collaboration between biochemist and physicist it is the biologist who must point the way and name the destination.

The second lesson learned from the cyclotron was a corollary to the first and might be stated thus. Isotopes do not solve problems. Isotopes plus intelligent biological conduct of the experiment and its ancillary concepts, techniques and analyses are capable of giving more answers than the concepts, techniques and analyses alone. The radioactive material and the Geiger-counter result do not provide solutions by themselves—it is their *biological context* which gives them meaning and significance. If this context is well planned and executed, the result is often of great importance if not, the radioactivity might as well have been allowed to decay quietly behind its lead shielding.

Now temporarily at least the cyclotron is somewhat less important in the medical picture. That colorful and temperamental device is undergoing expansion and perfection at the hands of its progenitors, the physicists. Its unpredictable vicissitudes have been replaced by forms in quadruplicate and on-the-clock delivery of materials formerly obtained only with difficulty. The cyclotron has given way to the chain-reacting pile (1 48

This new source of radioactive material in biological research has opened the way for investigators not situated in the established physical biological centers the pile makes these materials available to many rather than only a few of the country's surgical laboratories. Among the many newcomers to this field will be those who make the significant discoveries of the next decade their ability to produce worth-while information will be a function of preliminary understanding of the biologic problems they seek to solve. The more who set out, the greater likelihood of a few reaching the goal—and therein lies the true importance of the pile. It mass-produces a precious scarcity item.

I TYPES OF PROBLEMS

Although the types of biological research which may be carried out with radioactive isotopes are many they tend to arrange themselves into several significant subheadings.

1 *Permeability and membrane transfer.* In the study of the penetration of ions or molecules from one area of the body fluids to another isotopes make their greatest fundamental contribution to research. It is impossible to study certain types of membrane-permeability problems without tagged substances of some sort. Though one may place the red cell in plasma and carry out studies of the chemical constituents of the red cell and of the surrounding plasma, it is difficult to assess the permeability of the normal, healthy, red-cell membrane to its contained ions without the use of isotopes (6 50). The essential function of the isotope in this type of study is to allow the investigator to place all the material he is tracing in one or the other compartment and still maintain the system in chemical equilibrium. As one contemplates a red cell in its plasma it is apparent that there is potassium on both sides of the membrane. If the investigator alters the cell or its medium in such a way that the total chemical composition within the red cell changes by increasing its potassium content, it is of course clear that this potassium has come into the red cell from the surrounding plasma because there is no other source for it. But under stable equilibrium conditions such as those which obtain

in the body in the absence of disease one has no way of knowing whether or not any of the potassium within the red cell can exchange with the potassium in the surrounding medium unless there can be placed in the plasma a form of potassium which is identifiable once it gets into the red cell, as having come from the plasma. In such cell permeability problems, tagged substances provide the only means of obtaining a satisfactory answer. Whether that membrane be the capillary the lymphatic, the cell, the nucleus or some special barrier such as the glomerulus or choroid plexus, and whether the tracer be an ion or a large protein molecule, isotopic techniques inform the investigator of the relationships between the two sides of the membrane in a fashion which cannot be gained in any other way.

2 *Tracing metabolic pathways* Though we can dissect a whole animal and analyze its constituent organs chemically for an element we have no way of knowing the previous position of the element as found in the various organs nor its distance in point of time or metabolic pathway from its source such as the gastrointestinal tract. By the use of a tagged element it is possible to give one radioactive dose to the organism and at varying periods after administration to analyze the animal and find the position in the various organs and body fluids of this single dose. When one has analyzed the whole organism some hours after a feeding containing a radioactive element the distribution which one finds is presumably typical for the distribution of any similar amount of stable element administered the organism. The total dose given must be carefully considered in this type of work. The smaller the total gravimetric quantity of the element used (the more closely it approximates a true "tracer" dose) the more one may assume that its metabolism has been typical of the organism's handling of a single dose of that substance. If the radioactive material is given in a large dietary amount of isotopic mixture, then, of course, other problems such as toxicology and kidney function may be brought into play. By such studies of individual ions or elements much has been learned of the dietary metabolism of such substances as cal-

cium iron iodine and the physiologically important electrolytes. Now, with radioactive molecules of greater complexity becoming available more of this type of metabolic pathway mapping may be carried out relative to the metabolism of complex organic materials.

3 *Utilization by specific organs* As a refinement of the above investigation it is possible by means of isotopes to study the utilization of elements or compounds by specific organs. An outstanding example of this historically is the utilization by the thyroid of iodine (32-33). The physical and biological characteristics of iodine were in a sense a fortunate coincidence to the early workers in biology using radioactive isotopes. Certain radioactive isotopes of iodine are readily produced their physical emanations adapt themselves well to ordinary measurement techniques and the spectacular localization of nearly all of this element in one organ provided materials for tissue study which has yielded a mass of important information. Alteration of biological conditions either in the organism as a whole or in the tissue itself studies in tissue culture, studies in health and disease as well as methods of therapy have grown from this work. Had the radioactive isotopes of calcium sulfur, nitrogen, carbon oxygen and hydrogen been as readily applied to biological experiment as iodine has been what a mass of work already would have been accomplished on other important metabolic problems!

The autoradiograph presents the most intimate picture of utilization of elements or compounds by specific tissues and belongs in this category of observation. The autoradiograph is a record made on photographic emulsion by the beta radiation of isotopes previously administered to the animal or patient by comparison with microscopic slides and suitable magnification exact histochemical localization of isotopes may be obtained (3-45-46).

4 *External localization* The concept of injecting a radioactive substance into an animal or a patient and then casting about over the living organism with a Geiger counter to find out where the element went has gripped the imagination of investigators and public for many years. In the case of the thyroid the selective localization of the radio-iodine in

thyroid tissue wherever that tissue is, has provided again, by coincidence a ready application of such methods (33). Studies of the circulation by externally placed counters, using Na^{22} have also been carried out (63). Here however the lack of selective localization makes interpretation much more difficult. Attempts to collimate the beam of radiation by suitable screening of the counter occasionally help but such efforts nearly always interpose a greater distance between the radioactive source and the counting instrument in such a fashion that, by the law of inverse squares intensity is sacrificed for point localization. Experience with radioactive dyes and their localization in abscesses demonstrated that at least in the case of radiobromine external localization could best be produced by a minimum of shielding and also a minimum of distance between the radioactive source and the counting instrument (52, 65). The inverse square law is the investigator's best friend in this type of work. The intensity of counting rates using external counters on the intact organism is found to have a characteristic pattern for almost any element or compound used. Departures from this pattern are the significant finding and these departures are readily demonstrated if the normal distribution is well understood as a preliminary. Variations in thickness of the subcutaneous tissues and skin produce such differences in counting rates that quantitative relationships between dose and external measurement are difficult to establish except on an empirical basis.

5. **Tagging of complex compounds.** The study of complex compounds appears to represent a principal future effort in isotope research. Attempts to label complex organic materials with radioactive isotopes go back to the earliest days of the cyclotron. Many physiologically important molecules which contain such elements as carbon, phosphorus, iodine, iron or sulfur and which were susceptible of synthesis could be synthesized with the radioactive element in place of its stable isotope (13, 47). It should be mentioned in this connection that although gamma rays penetrate tissues to a depth of several centimeters their ionizing effect is localized in their immediate path and, hence, the lower ionization produced per unit of path and, hence, the lower counting efficiency in the measurement of gamma radiation.

61, 62) It is apparent from casual consideration of this problem that for the tracing technique to be valid the element involved must be in stable linkage in the organic compound. If one uses sodium or lithium salts of a compound with the radioactivity on the cation dissociation in solution separates the activity from the compound in question and subsequent counting rates are nonsignificant (72). Further such rapid metabolic breakdown that the tagging element is rapidly divorced from its chemical partner and subsequent physical analyses yield little information other than that concerning breakdown. In addition is the element made radioactive compounds were tagged by the extrinsic linkage of radioactive substances such as bromine or iodine (23, 66). These compounds provided much interesting information but occasionally suffered from the fact that the radioactive halogen or other element attached to the organic molecule so changed its behavior that physiologic measurements were misleading as regards the behavior of the normal substances in the organism.

The work of Schoenheimer and his co-workers with heavy nitrogen and deuterium has pointed the way for the future of this field (59). Their work and the work of Conant and Hastings with carbon (7) demonstrated the fundamental importance of using tracers from the biologically most important elements. By such techniques, paying careful attention to the precise chemical position of the tagging substance and the stability of the tagging linkage the physiologic behavior of most of the important compounds of the body may be studied. Compounds which cannot be synthesized in the laboratory may be made radioactive by using natural syntheses carried out by the living organism. Such methods have already yielded much information on hemoglobin metabolism (using radioliron) (50) and on protein metabolism (using sulfur) (61, 62). There are other examples where living organisms or bacteria have been used as a synthetic partner in such researches. The present availability of C^{14} has an almost front rank

importance in isotope research because of its use in the study of the more complex organic compounds

6 Fluid space measurement The measurement of volumes of body fluid available for the solution of an ion may be carried out by dissolving a tracer for that ion in the body fluid space in question allowing mixing to occur making appropriate corrections for excretion and then studying the final dilution obtained. The tracers used for this type of work have classically not been radioactive. The use of bromine as a tracer for chlorine allowed Hastings to make many of his fundamental observations on the extracellular space (67). The use of the blue dye as a tracer for plasma protein has enabled investigators to make measurements of the plasma volume (15, 24, 28, 41). Other techniques involving the use of isotopic tracers have developed measurements of the extracellular space (using radiosodium or radiochromine) (39) and total body water (using deuterium) (50). By the use of the same fundamental calculation the total quantity of other elements in the body may be determined. These methods will be dealt with in greater detail below.

7 Therapy with radioactive isotopes This is an application of radioactive isotopes dependent upon selective localization in pathologic tissues. In a sense this occupies a separate position from the strictly investigative use of the isotopes and as such will not be dealt with further in this article.

II. ARRANGEMENT OF PROJECTS

It is wise, in setting up a research project employing radioactive isotopes to follow certain general principles. The first of these has to do with physical collaboration.

1 Collaboration of physicists At the present time when pile produced isotopes are used the collaboration of a department of physics for the production of isotopes is no longer as essential as it formerly was. The co-operation of persons trained in radiochemistry is of vital importance if the investigator does not have at hand either the chemical or physical techniques required in the separation or preparation of isotopes for biological utilization. The most important aspect of this at

the present time has to do with safety precautions. Special equipment is required in the handling, purification, separation and dilution of isotopes which are received from the Atomic Energy Commission especially if these are shipped in the dry state. Commercial enterprises making such services available are coming into being at the present time and will remove a very real burden from the physicists.

For detection and measurement of isotopes in the tissues or body fluids which represent the end points of the investigation the help of the physicist is often required in the setting up or designing of apparatus. It is a mistake however to set up a research project with a detached physicist performing the sample measurements in a laboratory far removed from the biological aspects of the experiment. Under these circumstances the accurate correlation of physical and biological measurements which is so necessary to success is difficult. Furthermore this type of project in which the physicist is used simply as a technician to make or supervise the end point readings places the physicist and his laboratory in an unsatisfactory position and constitutes research by committee, a notoriously inefficient way of operating. If the isotopes used emit beta rays with energies sufficient to be measured on ordinary counting apparatus it is advisable for any research project to be organized in such a fashion that end point measurements may be made in the laboratory in which the biological experiments are carried out. The services and support of a well qualified physicist to help solve problems which come up relative to radioactive contaminants, double isotope experiments or measurements of unusual or difficult substances such as gases or weak radiation, should be available. Such a research project will be most successful if the physicist plays the rôle of consultant and is not relied upon too heavily for isotope preparation, sample measurements or biologic interpretation.

2 Cost of equipment The cost of research with isotopes is still greater than that of many other types of biological investigation. The necessary physical equipment at the present time costs approximately five hundred to one

In our opinion, the most vulnerable point in the technique of handling radioactive isotopes in medical investigation is the fingertip. There is little evidence that the amounts of radiation involved even with the use of isotopes emitting energetic beta and gamma rays will do damage to bone marrow or gonadal function *when only tracer amounts are involved*. However, fingertip contamination or even fingertip exposure might lead to serious subsequent injury. One should bear in mind that if the fingertip is 2 centimeters away from the flask and the sternum is 80 centimeters away the fingertip is receiving 1,600 times as much radiation as the sternum per unit of flat surface. Furthermore, the fingertip unlike the sternum or the region of the gonads, may be contaminated by liquid containing fairly high activities—as is found in a freshly diluted specimen of pile produced activity prior to injection into the animal or patient. Such fingertip contamination is notoriously difficult or impossible to remove. Anyone who has had experience in this area knows the consternation encountered when after scrubbing one's hands for 10 minutes they are placed under a Geiger counter and an intense discharge of counts is produced. This dramatically demonstrates the fact that in working with radioactive materials one is dealing with atoms and that they cannot all be removed even with a scrubbrush.

Protection of fingertips can be aided by the use of rubber gloves when high activities are handled. The rubber has no shielding value but it prevents actual liquid contamination of finger creases and fingernails. The use on the fingers of rings containing photographic film is still in an experimental stage and may add a useful precaution. However in the last analysis we come back to our old friends education, time, and distance.

If our present knowledge of exposure hazards and safety factors were complete it would be possible to list the late effects in human beings of the subclinical radiation dosages encountered in biologic research. That knowledge is not complete and excessive possibly unnecessary precautions are justified. One need only recall the damage and suffering which resulted from early and seemingly cau-

tious use of the roentgen ray to understand the necessity for excessive caution necessary in this field.

Precaution against injury should be uppermost in the investigator's mind—yet he should remember that the carrying out of certain standard forms of safety measures may also act as a precaution against liability. The storage of high activity samples behind adequate lead shielding checked by a monitor device (either counter or electroscope) in all six planes of the storage cube is an essential precaution. It is wise to place the storage unit in such a way that no personnel are steadily exposed to it though many may be intermittently exposed to infinitesimal doses by passing the neighborhood of the storage area.

2 Insurance Closely related to the subject of precaution against liability is insurance. Insurance may be divided into those policies which protect the investigator and his institution against justified claims arising from injury to qualified personnel while working under standard safety measures and on the other hand those policies which are written to protect the investigator or institution from claims arising from personnel not qualified or not associated with the research who have suffered psychic trauma or imagined physical injury as result of proximity to the radiation source either during shipment storage or use.¹ A third type of policy should be mentioned—that which covers liability for real or imagined injury to patients who have received injections of radioactive materials either for study or treatment.

The use of radioactive materials is not widespread enough at present to fall into 'standard practice' and the range of liability is as yet undefined.

Of these three types of policy the first would appear to be the most essential. Late radiation injury might not manifest itself for years and workers who handle activities of any magnitude should be protected against the

¹ An example of the expense of such "public liability" policies may be gained from the fact that a premium of \$150 per shipment has been quoted for policy with limits of \$100,000 per individual payment and \$300,000 per total collection for any one suit. Property damage of \$5,000 per accident was included. This quotation was for K⁴⁰ in air transit. This premium may go up to \$1,500 if the consignee accepts full responsibility from the shipping point.

leaving only residual amounts in plasma though equilibrium is much more slowly attained. Isotopes injected as a part of organic compounds will, of course, follow the distribution of that compound or its breakdown products. Frequently considerable trial and error are necessary to establish the minimum dose which will yield satisfactory readings hours or days later when the measurements are made. In animal work the use of a minimum allowable dose is less important than in human studies though in either case the use of unnecessarily large radioactive doses constitutes a hazard to those injecting the original more-concentrated solution, and may in certain cases (Example iodine) actually alter the manner of utilization by direct radiation effect on the cells which take it up (58). In studies made with human beings the importance of avoiding overdosage in tracer studies is self-evident.

Time relationships as they affect dosage naturally depend on the relation of experiment-duration to half life of the material (Table I). The longer lived isotopes such as Fe^{59} , P^{32} , Ca^{45} , S^{35} , and C^{14} (Groups 3 and 4 Table I) present little problem. Those in Group 2 (Na^{24} , Br^{80} , K^{42}) present a real problem since inordinately high initial dosages may be necessary if the experiment is to last several half lives before end point measurements are made. With this group of isotopes very careful timing and dose calculation must be carried out to avoid high dosage and radiation effects on man or animal or on the other hand a failure from readings too close to background. In the short lived group (Cl^{38} , C^{11}) time looms larger than anything else in planning the dosage and conduct of the experiment. In both the latter groups of isotopes measurement techniques which concentrate the element in question or which employ crude extracts of large amounts of body fluid or tissue may help the investigator over the hurdle of short half life though when such methods are used careful account must be taken of self-absorption.

2 *Measurement* Just as the biologically important isotopes may be grouped according to their half lives so may they be grouped according to the energy of their beta rays and

TABLE II — RADIOACTIVE ISOTOPES OF COMMON BIOLOGICALLY IMPORTANT ELEMENTS ARRANGED ACCORDING TO ENERGY OF EMITTED PARTICLES

Element	Isotope	Particle energy in Mev (Max)	Gamma radiation Mev (Max)	
Hydrogen	H	0.015 e ⁻		Group 1. Radiation energy less than 1 Mev; technology of detection complex and still developmental.
Iron	Fe^{59}	0.06 Mev X-ray		
Carbon	C^{14}	1.45 e ⁻		Group 2. Radiation energy from 0.1 Mev to 1 Mev; technology of detection now available but close attention must be paid to problems of self-absorption, and special equipment may be necessary for accurate measurement.
Sulfur	S^{35}	0.70 e ⁻		
Calcium	Ca^{45}	0.20 e ⁻		
Zinc	Zn^{65}	(0.400 e ⁻) ¹	1.4	
Iron	Fe^{59}	0.60 e ⁻	3	
Bromine	Br^{80}	0.65 e ⁻	0.33	Group 3. Radiation energy over 1 Mev may be measured with ease on standard commercial equipment, hazards of handling "tracer" quantities greater than 1 Group 2 and
Sodium	Na^{24}	0.58 e ⁻	0.30	
Iodine	I^{131}	0.60 e ⁻	0.37	
Iodine	I^{130}	0.70 e ⁻	0.54	
Nitrogen	N^{13}	0.20 e ⁻	0.18	
Sodium	Na^{24}	0.4 e ⁻	0.73	
Phosphorus	P^{32}	0.60 e ⁻		
Oxygen	O	0.20 e ⁻		
Magnesium	Mg^{28}	0.60 e ⁻	1.0	
Carbon	C^{14}	1.40 e ⁻		
Potassium	K^{42}	1.58 e ⁻	1	
Chlorine	Cl^{38}	1.00 e ⁻	1	

¹Produced only on cyclotron; the present time particle emission is small fraction of disintegrations and therefore of little significance in measurement.

hence the ease and technique with which they may be measured (Table II). The "strong" group includes Na^{24} , K^{42} , Cl^{38} , P^{32} , I^{131} . These are easily quantitated with standard equipment readily obtainable. The middle group S^{35} , Ca^{45} , Fe^{59} require special attention to self-absorption counter or electroscopewindow thickness and methods of concentration, purification, precipitation or electroplating. The weak group H^3 , Fe^{59} present such problems in measurement that techniques are still in process of development and it is possible that the most practical and reliable have not yet

It will be observed in Tables I and II that many of the elements of weakest radiation have the longer half lives as a general rule half life and particle energy are inversely proportional. There are certain outstanding exceptions such as oxygen (O^{15}) and magnesium (Mg^{28}).

go up, down, or sideways it may never reach the counter window because of absorption in the universe of Na^{24} around it, or because it never started out with enough energy to get to the counter. It may be stopped in the counter window or, as a final insult it may pass through the counter so soon after its immediate predecessor that the counter itself has not recovered from the previous discharge in time to register its passage. It is therefore clear that all the electrons emitted by the Na^{24} do not cause a pulse to pass through the scaling circuit. When one considers that the absolute units of radiation intensity, the curie and the rutherford, are based on rate of disintegration it becomes clear that accurate quantitation of radioactive isotopes involves a measurement of the absolute disintegration rate of that material in terms of 'disintegrations per unit time. In dealing with ordinary counting equipment and under the geometrical conditions ordinarily employed this problem is one to confound the biologist and give pause even to the physicist.

A curie is defined as the quantity of radon in radioactive equilibrium with 1 gram of radium, and involves a disintegration rate of about $3.67 \pm 0.03 \times 10^{10}$ disintegrating atoms per second per gram of radium. This unit should properly not be applied to radioactive substances outside the radium family.¹ The rutherford is defined as that amount of any radioactive isotope which disintegrates at the rate of 10^6 disintegrations per second. Complicated physical techniques are required to measure the absolute disintegration rate of Na^{24} . However by the use of suitable standards calibrated with samples of known radioactive strength one may approximate for purposes of rough estimation just what a microcurie or a millirutherford, of Na^{24} will yield on one's own instrument in terms of counts per minute. The only importance which attaches to this has to do with radiation hazards. Successful biologic experiments may be carried through without any reference to absolute standards. Results may be expressed

The reader is referred to the much fuller discussion in the report, "Radioactivity Units & Standards," prepared by Professor Robley D. Evans, of the Massachusetts Institute of Technology for the National Research Council, Division of Physical Sciences, Committee on Radioactivity Subcommittee on Units, April 3, 1947.

In terms of the injected dose, or counting rate or in "units relative to uranium or other arbitrary standards or in any way which is clear and unequivocal. But it is important for the safety of both workers and subjects to know to a first approximation the absolute disintegration rate of the starting material for only in this way can the investigator relate his safety precautions to the experience of others.² This knowledge is probably easiest

*Calculation of the roentgen equivalence of systemically administered radioactive isotopes involves many pitfalls. The extent of tissue dilution, the phase volume of body water in which the isotope is diluted and specific tissue affinity are biologic variables which must be taken into account. The physical aspects of converting tissue dosage from beta rays into roentgens (units of radiation based on air ionization) are complex. In many instances only an approximation can be calculated for this conversion.

Two simple formulas have been derived by Prof. Robley D. Evans of The Massachusetts Institute of Technology which are quite useful in this connection. The first formula is an expression whereby one may calculate the daily dosage rate in roentgens per day (R) derived from an isotope which achieves an average tissue concentration (C) in millicuries per kilogram, and possessing an average particle energy (E_p) measured in MEV.

$$R = 60CE_{p^2} \quad (1)$$

It should be emphasized that R is a *massal* value; the formula is applicable when the isotope is dispersed through a mass of tissue large enough so that the mean beta ray path falls within the tissue surface is small compared to mass. For simple beta-ray spectra the average particle energy may be taken as $\frac{E_{max}}{3}$.

When a gamma ray is also involved, the roentgen equivalence is increased by 10-20 per cent. This formula is most useful in dealing with long half-lived materials.

When a short half life isotope is involved, the total dose is a more important calculation than the daily dose. Here the following formula applies:

$$D = .44 RT \quad (2)$$

where D is the total dose in roentgens, R the initial daily dose rate arrived at by formula (1) and T the half-period in days.

An example of this calculation may be illustrative. Suppose an 80 kgm. man is given 0.6 MC of K^{40} . The isotope may be considered as diluted in all of body water (60 liters). Then

$$R = \frac{(60CE_{p^2})}{3} =$$

$$R = 60 \times 0.01 \times \frac{1.5 \times 10^6}{3}$$

$$R = 0.857 \text{ roentgens per day (initial dosage rate).}$$

The factor ($\frac{1}{3}$) is the correction for the presence of a gamma ray. Since K^{40} is a short lived isotope (1.4 hours) the radiation delivered to tissue by the end of the first day is in the order of $\frac{1}{4}$ that being delivered at the outset, so the half life correction should be introduced, and the total dosage calculated:

$$D = 1.44 RT$$

$$D = 1.44 \times 0.857 \times 0.5$$

$$D = 0.62 \text{ roentgens total dose.}$$

This first approximation of the radiation dosage to which the patient has been subjected for study should be considered with the fact that the generally regarded safe limit is 0.6 roentgens per week. Thus the K. study could be repeated at weekly intervals indefinitely and fall within this margin of safety. Ordinary x ray exposures involve total radiation of 3-5 r for a chest fluoroscopy and film, 60-80 r for a gastrointestinal series.

These formulas are discussed more fully in the article by Professor Evans entitled "Dose Dosage in Radioisotope Therapy," *Am. J. Roentgen*, December 1947. The formulas were presented at the 1946 meeting of the American Roentgen Ray Society Symposium on Isotopes. The reader is also referred to the calculations described by W. E. Cohn in the Manhattan District Declassified Reports, 246, 95; July 4.

Fig. 2. Diagrammatic representation of a chemical situation in which physical (isotopic) equilibrium takes place despite net chemical transport in the opposite direction. Symbols and arrangements are as in Figure 1 except that the "In" compartment contains four times normal saline (3.2%) which produces an osmotic readjustment resulting in the net transport of sodium and chloride ions from "In" to "Out" before chemical equilibrium is re-established.

The addition of Na²⁴ to the "Out" compartment produces a movement of radioactive ions from "Out" to "In," exactly as in Figure 1.

It is clear that the radioactive data alone in such a situation might be most misleading as to the true nature of the chemical process taking place.

cate differences in permeability to sodium in the presence of 'bound' sodium which is not exchangeable or failure to achieve equilibrium in the time elapsed.

Much radioactivity research with ions has suffered from a lack of concomitant chemical analyses and, hence, an absence of specific activity data. Even in work with more complex organic compounds calculation of the specific activity will often reveal interpretative data not available from either physical or chemical analyses alone (10).

2 Physical equilibrium vs chemical transport If one were to make a gastric pouch and place therein a quantity of radioactive chloride sodium, or even deuterium the isotope would be seen to disappear from the pouch (4, 8, 9, 19). It would appear that the ion in question were being absorbed from the pouch. It was placed there and now it is there no longer—surely the cells are actively absorbing the substance in question.

Such is not necessarily the case. Even if the gastric mucosa were actively secreting HCl at the moment, the Cl³⁵ would still diminish both in total amount, concentration and specific activity. The fact is that the

Geiger counter and the cyclotron have put into our hands a means of detecting atomic quantities and we must no longer think in milligram terms when dealing with these unmeasurable weights.¹

It is a fundamental assumption of all research with isotopes that the living cell, just as the passive membrane cannot distinguish between isotopes of the same element. There appear to be a few interesting exceptions to this (Examples H², H³—or I¹³¹ in high concentration 40) but as a fundamental assumption it is sound. Therefore as mixing of atoms occurs a state of equilibrium develops in which unstable atoms are mixed with the same number of stable atoms in all parts of the system. The simplest example of this phenomenon is a unimolecular solution of ions free of all externally induced motion—an absolutely still beaker of KCl for example. This

¹In the most concentrated radioactive mixtures ordinarily available, only one-millionth or less of the atoms are unstable and capable of emitting radiation on stabilization. Only in the new "carrier free" products of nuclear fission have pure radioactive preparations of the man-made isotopes been produced; and even here, if half life is short and decay yields stable isotopes of the same element, radioactive purity will rapidly give way to diminishing specific activity. Long lived carbon C¹⁴ obtained from the Atomic Energy Commission contains about 3 per cent active atoms.

Fig. 3. Diagrammatic representation of a biological situation analogous to that shown in Figure 1. Although chemical equilibrium (stability) between potassium in the red cell and plasma is maintained by the peculiar properties of the viable erythrocyte, physical redistribution occurs following the addition of K^{42} to the plasma by intravenous injection. Such an injection upsets the proportional distribution of isotopes and, as a result of the permeability of the red cell membrane to potassium, equilibrium is re-established slowly. The nature of the curves suggests that a fraction of the potassium in the red cell is only slowly exchangeable with plasma potassium. Analyses either for K^{41} (chemical) or K^{42} (physical) do not reveal the nature of the events; only by simultaneous analyses for both may the situation be depicted.

system is, of course, not really motionless except at absolute zero as Brownian movement and infrared emission dissipate the thermal energy of the solution at room temperature. If it were possible to introduce into this apparently motionless system without disturbing it, a droplet of $K^{42}Cl$ the $K^{41}:K^{42}$ ratios in any area of the solution rapidly would become constant, as an expression of the attainment of physical equilibrium.

Early physicists who studied the difficulties of attaining and maintaining a vacuum stated that 'Nature abhors a vacuum.' This might be paraphrased to state that 'Nature abhors the separation of isotopes.' Energy must be expended to separate isotopes of the same element and given an opportunity to do so the separation will yield again to proportional distribution.

If the droplet of $K^{42}Cl$ introduced were in the form of a globule surrounded by a permeable membrane, and containing within it a KCl solution of exactly the same concentration

as that in the beaker the same equilibrium would occur. But the amount of KCl in the globule would not be altered. Physical equilibrium has taken place without chemical transport by way of analogy the radioisotope has disappeared from the gastric pouch without necessarily indicating any net absorption of sodium. Atoms have moved not milliequivalents. Actually the disappearance of K^{42} from the globule of KCl in the beaker is a measure of permeability to not transport of the ion, using the term 'transport' to mean the movement of enough atoms to alter the chemical concentration of the total isotope mixture on one side or the other of the membrane in question.

This confusion of physical equilibrium with chemical transport may be a source of error in the interpretation of results only by concomitant measures of radioactive and stable isotopes (i.e. physical and chemical analyses) and the calculation of specific activity may such confusion be avoided (Figures 1, 2, 3 and 4).

3. Phase measurements: The use of isotopes to measure areas of body water or the total

*This and the subsequent chart are based on work now in progress under contract with the Office of Naval Research and Harvard University.

Fig 4. Diagrammatic representation of a biological situation analogous to that shown in Figure 2, and in contrast to that shown in Figure 3. The poorly preserved erythrocyte, *in vitro* is releasing its potassium as a preliminary (or accompaniment) of hemolysis. The K^+ added to the system still enters the red cell, and with an increased rate, as normal permeability relationships are upset by the "death" of the cell. As in Figure 2, net chemical transport (concentration or distribution alteration) is taking place in a direction opposite to that taken by the "tracer." Only by concomitant physical and chemical determinations may such a situation be revealed. It is of interest that the nonviable erythrocyte appears to have lost its non-exchangeable moiety of intracellular potassium.

amount of solid bodily constituents involves a simple concept, the formula for which is illustrated by analogy in Figure 6. The accuracy of this determination will depend upon the statistical accuracy of the "specific activity" figure employed in the final ratio in terms of Figure 6, the ratio of black to white apples in the fair sample taken after mixing.

This method may be used to serve three types of application in biological research. The first involves the use of nonisotopic materials for the measurement of fluid volumes; the second involves the use of isotopes for the measurement of fluid volumes; and the third embodies the use of isotopes to measure the total quantity of certain solid (ionic or elementary) constituents of the body.

In the measurement of areas of body fluid calculation depends upon the familiar formula for dilution

$$C_1 V_1 = C_2 V_2$$

where C_1 and V_1 represent the concentration and volume of solute in solvent before dilution and C_2 and V_2 after dilution. C_1 and V_2

are known to begin with. C_2 is measured after mixing and V_2 may be calculated

$$V_2 = \frac{C_1 V_1}{C_2}$$

The use of dyes to measure plasma volume is the earliest and most widely used application of this principle to biological work; it dates back to the work of Keith, Rowntree and Geraghty (41). When this method is used the "tracer" is detected by color instead of by radiation or weight and constitutes a tracer not because it resembles any of the normal constituents of the plasma (though Evans blue has colloidal properties not unlike albumin in aqueous solution) but because it is a dye which forms a nonpolar bond with plasma protein (largely albumin) at low temperatures (5, 57). It, therefore, in actuality measures the "albumin space," and its complex disappearance curve is partly the result of the fact that a significant moiety of plasma albumin circulates outside the plasma.

Ideally, the perfect tracer to use in measuring a body fluid space is an isotope of a normal constituent of that space which rapid

Fig. 5. Diagram illustrating some of the methods now available for the measurement of "phases" of the body fluids. References to the technical procedures involved are to be found in the text.

ly equilibrates in the total isotopic mixture and after an initial mixing phase presents a flat disappearance curve at any point in which a fair sample may be removed to determine C_2 and solve the equation for V_2 . Though the dye departs widely from this theoretical ideal its extensive use and study by Gibson, Gregersen and others has rendered it a highly useful device (2, 24, 27, 28, 37, 38).

The employment of thiocyanate ion is another nonisotopic application of this principle used to measure the volume of extracellular fluid available for thiocyanate solution (14, 20, 29). Thiocyanate is an anion similar in many respects to chloride and used in essence as a tracer for chloride. It is determined chemically by colorimetry. Like the dye, it is foreign to the body (though some individuals may carry basal concentration of 0.2 to 0.5 mgm per cent a fact which must be determined in all SCN space measurements) and in addition it is slowly removed and may be toxic in high concentration. Repeated determinations leave residual quantities in the serum which render each successive determination less accurate as the injected quantity constitutes a progressively lesser increment over the basal concentration.

The use of radioactive isotopes of iron (as hemoglobin synthesized in a donor who has been given the radio-iron) to measure the red cell mass is a theoretically perfect application of the tracer principle to a space measure-

ment (25, 26, 51, 55). The radioactive noncontaining red cells from the donor mix with the recipient's cells like the apples in the barrel; they do not escape into other compartments and the disappearance curve is essentially flat for long periods being affected only by cell destruction or the slow formation of new cells from dietary iron. From a practical standpoint the chemical processing to which the cells must be subjected prior to electroplating and the weak x-ray emitted by Fe^{59} which makes detection difficult contrive to render this method cumbersome although widespread investigative application is feasible.

The use of Na^{24} to measure the extracellular fluid—the sodium space—is practical and readily available (39, 69). From a theoretical point of view it is not perfect since after initial mixing the disappearance curve is not flat but drops slightly as sodium penetrates cells and is incorporated into bone. Just as with the dye-plasma method, this leakage of the tracer into another area may be compensated by adopting a standard sampling time early in the curve.

The use of deuterium for measurement of total body water is another "ideal" application of the tracer principle to body fluid space measurements (34, 35, 43, 49, 50, 54). Although deuterium has twice the mass of H^1 , this weight difference does not appear to interfere with applicability; the use of H^3 might be seriously hampered by this mass

change.¹ Deuterium exchanges with the exchangeable hydrogen in organic compounds as well as with H_2O but this amount is quantitatively so small as compared with the great volume of body water that it escapes measurement unless one isolates the end products of that exchange or the compounds synthesized by the body in the presence of deuterium rich H_2O . The physical apparatus necessary to measure plasma deuterium by gravimetric means is not complicated and the measurement of total body water by this technique is available now that D_2O has been released for general use by the Atomic Energy Commission.

The measurement of total solid constituents by the use of isotopes involves the same fundamental considerations, the concentration however, is not the radioactivity per unit volume of solvent but is instead the actual isotopic concentration—the radioactivity per unit weight of isotopic mixture—in short the specific activity (50). Thus C_1V_1 becomes the total radioactivity injected, C_2 the specific activity after equilibrium has occurred and V_2 the total amount (in terms of weight) of isotopic mixture in which the isotope has become mixed.

The measurement of total body sodium by this method consists in measuring the specific activity of the plasma sodium after equilibrium has been attained (24 to 36 hours) and dividing this ratio into the total activity injected at the outset. The urinary excretion should be subtracted from the injected activity the quantity excreted in the case of radiosodium is small.

Total body potassium may be measured by the same technique though urine excretion is significant and must be measured. The selection of what constitutes a fair sample of exchanged potassium is more complex. Studies now under way in this laboratory on K^{42} at equilibrium with K^{39} in the human body indicate that the urine specific activity after 30 hours represents exchange conditions throughout the body providing that dietary

Fig. 6 An analogy devised to illustrate the principle involved in the determination of total exchangeable constituents by the tracer method.

The number of white apples in the barrel is unknown. A known number of black apples similar in size and shape the "tracers," are added to the system. Mixing is produced, and a "fair sample" is then removed for examination. The ratio of black to white apples is determined, and from this ratio the total number of apples in the barrel is calculated as shown.

In the biologic experiment, the unknown number of apples finds its analogy in the total quantity of ions to be measured. The "tracer" is the isotopic material to be mixed in the body. The "fair sample" is the tissue or fluid measurement made at equilibrium, and the ratio of black to white apples is the "specific activity" under equilibrium conditions. The final calculation consists in dividing the specific activity into the total activity present in the organism, to determine the total quantity of ion with which the isotope has exchanged.

K is limited prior to measurement of the urinary specific activity. The red cell originally conceived as a satisfactory barometer of the K^{42} / K^{39} ratio at equilibrium has been found to be unsatisfactory because of the apparent presence therein of nonexchangeable or slowly exchangeable potassium. Muscle, liver, plasma and urine are in equilibrium after 24 hours (16 18 22 53 70). Muscle and liver are of course not readily obtainable for sampling. Plasma, because of its low K^{39} content has low K^{42} values under conditions of physical equilibrium. The urine therefore constitutes the most readily available source of K for study of K^{42} / K^{39} ratios and calculation of total exchangeable K.

¹The work of Pace, et al. (J. Biol. Chem., 1947, 168, 459) employing "tritiated water" (HTO) to measure the total body water suggests that hydrogen of mass 3 is actually correct from a practical viewpoint despite the theoretical objection raised by the mass increment.

Dietary K finds a high representation in urinary K because the excretion rate of K is directly proportional to the plasma concentration over about 5 mE/L (71). For this reason the total body (exchangeable) K measurements must be made after a 12 hour K free fast—an overnight fast being sufficient for this purpose.

Methods for the measurement of total exchangeable nitrogen carbon sulfur and phosphorus could similarly be worked out in each case special problems of determining C_2 and the exact anatomicochemical extent of V_2 will arise and must be settled to establish the validity of the result¹.

The application of these measurements of total body constituents to the pressing problems of surgical nutrition and preoperative and postoperative care may lead us to a more quantitative concept of the needs of the surgical patient.

SUMMARY

1. Some practical problems relative to the biological use of isotopes are briefly discussed.

2. An increasing application of these methods to the problems of surgery may be expected in the future.

3. Such application will be most fruitful if adequate attention is paid to the fundamental biology of the problem at hand and to the basic considerations relative to all isotope research.

¹The work of Wintrobe and his group (*J. Biol. Chem.*, 1945, 165: 207) on the "labile iron pool," measured by the dilution of radioactive iron, represents an extension of this principle into the complex problem of iron distribution and metabolism, the measurement is essentially that of the "total exchangeable iron."

THE RECTOGENITAL SEPTUM

EDUARD UHLENHUTH, Ph.D., WALTER M. WOLFE, M.D. E. MILTON SMITH, M.D.,
and EDMUND B. MIDDLETON Baltimore, Maryland

CAUDAL to the peritoneum of the rectovesical pouch in the male, the rectum and the bladder (together with seminal vesicles and prostate gland) are separated from one another by a relatively thin layer of tissue. In this tissue is found a membranous septum which is closely attached, by its cranial margin to the peritoneum at the bottom of the rectovesical pouch, and adheres, by its caudal end to the dorsal surface of the prostate gland. For this membrane the term of "rectovesical septum" has been in use for some time in conventional anatomy.

A similar septum is found almost without exception in the female between the rectum and the vagina in conformity with the nomenclature employed in the case of the male it should be called the rectovaginal septum. To denote the male and female septa collectively we will use in this article the term of rectogenital septum.

For several reasons this septum is of considerable importance. In the first place it separates the rectum from the bladder seminal vesicles, and prostate gland in the male, and from the vagina in the female. And furthermore it is to be counted among the structures which constitute the supporting mechanism of the genitourinary organs. Finally as will be discussed in another article this septum in combination with certain fascial sheets, effects a complete division of the subperitoneal space of the pelvic cavity into a dorsal or rectal compartment and into a ventral or urogenital compartment.

Concerning the nature of the rectogenital septum two opinions are in existence according to one of them it is of peritoneal origin while according to the other one it would be a purely fascial structure.

From the Department of Gross Anatomy University of Maryland, Medical School.

These investigations were supported by grants from the Weaver Fellowship Fund of the University of Maryland Medical School.

Briefly the history of our knowledge of the rectogenital septum is as follows. The tissue between the rectum and bladder in the male was investigated first by Denonvilliers in 1836 hence urologists are still using the term

"Denonvilliers fascia" for this tissue in the male. Later on in 1899 two other French men Cuneo and Veau studied the "fascia prostatopentonealis" from an embryological point of view and arrived at conclusions which, in the opinion of the authors of the present article, are valid up to the present day. According to Cuneo and Veau the prostatopentoneal fascia (our rectovesical septum) is a peritoneal derivative and results from the fusion during embryological development of the ventral with the dorsal wall of the rectovesical pouch which in early embryological stages extends all the way down to the pelvic floor. In 1922 Miley B. Wesson reinvestigated the rectovesical septum and refuted the views advanced by Cuneo and Veau. On the basis of embryological studies this author claimed that the rectovesical septum is of fascial nature. The most recent publication on this subject is an article by Tobin and Benjamin and represents again an embryological investigation the results of which, however, were confirmative of the interpretation which Cuneo and Veau gave to the rectovesical septum.

Another quite recent article (1940) must be mentioned here. As we will see later on we have never had any difficulty either in the student dissecting room or in special dissections, to display the rectovaginal septum in the female cadaver. Curtis Anson and Benton however were evidently not able to find a rectovaginal septum. On p. 649 (2) they describe the tissue located between the rectum and the vagina as being composed of the fascial envelopes of rectum and vagina, with some "cellular tissue" intervening between them.

Since certain observations in adult cadavers seemed corroborative of the views of Cuneo and Veau, the senior author of this article has long been accustomed to teach the subject of the rectogenital septum to his students in the light of the studies made by these two French anatomists. Later on however when we became familiar with Wesson's article refuting the pentoneal theory of the rectovesical septum, we found it necessary to reinvestigate this problem and, more especially to record our observations by suitable illustrations. Since 1939 we have collected a large number of observations some of which will be reported in the present article.

It is our object to report, in the first place certain details which can easily be observed in adult cadavers and which can best be explained in the light of the pentoneal origin of the rectogenital septum. In the second place some observations in infants will be discussed which show that even during late intrauterine life the rectogenital pouch continues to recede from the rectogenital space.

OBSERVATIONS IN THE ADULT

Our attention was devoted mainly to the relation between the rectogenital septum and the peritoneum of the rectogenital pouch and further to the configuration of the peritoneum along a line corresponding to the attachment of the septum. But incidentally we also have made measurements to determine how far caudally the rectogenital pouch extends.

1 Caudal extent of rectogenital pouch It is generally assumed that in the female the rectovaginal pouch reaches down further caudally than the rectovesical pouch does in the male. On the average the bottom of the rectovesical pouch is said to lie 3 inches above the anus the bottom of the rectovaginal pouch only 2 inches. Because of the scarcity of female cadavers we had no opportunity to study the variations in the level of the rectovaginal pouch. In one female, illustrated in Figure 5 a colored woman 29 years old (479a, 1946), the bottom of the rectovaginal pouch was located 35 millimeters cranial to the ventral commissure of the anus. In another female cadaver (479a 1944), of a colored woman aged 35 years (see Fig 6), only the distance between

the bottom of the pouch and the pelvic floor was measured, it was 58 millimeters, i. e. over 2 inches to conclude from this value the bottom of the rectovaginal pouch in this female must have been located nearly 3 inches cranial to the anus i. e. nearly twice the distance which it had in female 479a, 1946.

In males we have made a larger number of measurements. In Table I the cranial distances of the bottom of the rectovesical pouch from the ventral commissure of the anus, as measured in midsagittal section through the pelvis are listed for 23 male pelvises. One glance suffices to make one realize that the variability of this value is very considerable (from 34 to 78 mm.) Only in 6 among the 23 cases, the bottom of the rectovesical pouch was found 3 inches or slightly more (74 to 78 mm) cranial to the anus. In 8 cases the pouch was located only about 2 inches (from 48 to 58 mm) above the anus, and in 1 case this distance was only 34 millimeters (1½ inches) i. e. less than the assumed average in the female.

connective tissue. Moreover careful examination of the inner surface of the peritoneum at the bottom of the pouch failed to reveal any special features of this peritoneum, such as are found when a septum is present, and will be discussed in the following paragraphs.

In Figure 2, the right half of the pelvis of a white male, aged 69 years (4794, 1945) is illustrated. In this subject the bottom of the pouch was located well above the prostate gland. Attached to its outer surface is seen the rectovesical septum which could be displayed with great ease and perfectly clearly. As is always the case in the male it was separated from the rectum by a quantity of loose connective tissue which could be easily broken down with the finger. Ventrally it was more closely adherent to bladder and seminal vesicles from these structures it was raised with the aid of a blunt instrument as far caudal as the prostate gland. On the dorsum of the gland it faded away into the fascial capsule of this organ. Inspecting the peritoneum of the pouch on its inner (cranial) surface we observed running transversely and corresponding to the line of attachment of the rectovesical septum on the outside, a slightly grooved line of whitish color, which resembled a scar such as remains after a surgical suture. Along this line and on either side of it, the peritoneum was slightly wrinkled perpendicularly to the line. This configuration of the peritoneum is particularly conspicuous, as everywhere else in the pouch the peritoneum is perfectly smooth and devoid of irregularities. As is usually the case, the scar like line extended laterally on either side where the walls of the pouch rise along the lateral walls of the pelvis corresponding to a cranial continuation of the rectovesical septum into lateral peritoneal wings of the pouch. As has been described in another article (6) these lateral wings serve for the attachment of the peritoneal pouch to the visceral endopelvic fascia. The location and direction of the line both corresponding to the line of attachment of the rectovesical septum as well as the appearance of the peritoneum along this line leave no doubt that it represents the line along which the dorsal and ventral walls of the pouch fused with one another.

Another similar case but with the line of fusion even more conspicuous, is illustrated in Figure 3. It pictures the right half of the pelvis of a male negro (4794, 1945) aged 51 years (measurements recorded in Table II). The rectovesical pouch was located well above the prostate gland (25 mm) and a well developed rectovesical septum was present. Again a whitish scar like line was present on the inner surface of the pouch, which corresponded in location exactly to the line of attachment of the rectovesical septum on the outside. In this case the whitish line was even more conspicuous than it was in the previous case, as it was more irregular and crossed in several places by cord like thickenings of the peritoneum. From its midpoint in the median sagittal plane it extended laterally on either side for a distance of 41 millimeters having thus a total length of about $3\frac{1}{2}$ inches.

There is another feature which is shown in this illustration. We made a special attempt in the dissection of this pelvis to ascertain the relation between the rectovesical septum and the fascial capsules of rectum and bladder. As is shown in the illustration, each of the three membranous structures was dissected and displayed individually. As in the previous case the rectovesical septum was closely adherent to the bladder and prostate gland but was separated from the rectum by loose connective tissue. It could be followed as an individual sheet of tissue all the way down to the pelvic floor. Cranially it was continued without any discernible boundary or change in texture into the peritoneum of the rectovesical pouch. With similar distinctness we were able to display the fascial capsules of the rectum dorsally and of the bladder and prostate gland ventrally. Contrary to the description given by Curtis Anson and Beaton for the female pelvis the rectovesical septum is a structure additional to and independent of, the fascial capsules of the adjacent viscera. Attention should be called also to a condition of the capsule on the ventral surface of the rectum which we have encountered in many other cases. The ventral capsule of the rectum as shown in Figure 3 was attached cranially to the peritoneum of the rectovesical pouch slightly above the line of attachment of the

septum. From this level on cranially the ventral capsule of the rectum. If there was one could not be displayed gross anatomically as a layer independent of the peritoneal covering of the rectum. In connection with this condition it should be pointed out that the rectovesical septum could be distinguished clearly from the fascial capsules as will be referred to again; its texture and color were different from those of the fascial sheets.

In Figure 4 (4794 & 1945) an extreme case of the "scar" at the bottom of the rectovesical pouch is illustrated (for measurements see Table II). In this subject a colored male aged 47 years this line extended far laterally rising up cranially along the lateral wall of the pouch where on the outside a well developed lateral peritoneal wing was attached to the pouch. Its line of attachment corresponding exactly to the location of the linear "scar." While elsewhere in the pouch the peritoneum showed a perfectly smooth surface it was thrown along the whitish line into many wrinkles and coarse folds running perpendicular to the line and creating the impression that some secondary processes of reorganization had taken place in this region during development. In addition a series of strong peritoneal cords had developed which were running in dorsoventral direction bridging over the line of fusion. Obviously these cords must have had the effect of re-enforcing the line of fusion preventing a secondary splitting of the septum into its two original layers. Seeing this line and its accessory formations in a specimen as the one described above one could not be in doubt that the rectovesical septum is the result of fusion of the dorsal and ventral wall of the rectovesical pouch with one another. This line corresponds exactly to the line of attachment of the septum; it is the only place in the pouch where the peritoneum is not smooth and the peritoneal structures developed along this line have the effect of preventing a reopening of the fused portion of the pouch.

The rectovaginal septum of the female pelvis is illustrated in Figure 5 picturing the left half of the pelvis of a colored female (4901046) aged 29 years. In this subject however the mode of attachment of the septum to the peritoneum differed from the specimens de-

scribed previously. The peritoneum at the bottom of the pouch was carefully examined but neither the whitish "scar" nor any signs of processes of reorganization could be detected. The cranial end of the septum was split into two leaves: a ventral and a dorsal leaf each of these was attached separately, the ventral leaf was continued without discernible boundary into the ventral and dorsal wall, respectively of the rectovaginal pouch. Across the gap between the two limbs, the peritoneum of the pouch had grown as a continuous peritoneal partition separating the space of the gap from the peritoneal cavity and at the same time re-enforcing the line of fusion in the middle as a binder. Obviously this is only a special case of the peritoneal cords. Instead of cord separated from one another by varying intervals the peritoneum had grown over the gap between the two leaves of the septum as a single continuous sheet.

As in the male, the fascial capsules of the viscera adjacent to the septum could be displayed as structures entirely separate from the septum (Fig. 5). Moreover as in the males, the ventral capsule of the rectum was attached cranially to the peritoneum of the pouch and could not be demonstrated cranial to this level as an individual layer. As the illustration shows the same condition existed with respect to the capsule of the vagina beyond the level of its attachment to the peritoneum of the pouch over the body and fundus of the uterus, no individual capsule could be demonstrated a condition which, however, is well known.

We observed in this specimen before a dissection was made that the rectovaginal septum passed from its cranial attachment forward to the dorsal wall of the vagina which it was closely adherent while distal it was separated from the rectum by a considerable space filled in with loose connective tissue. When the uterus and with it the vagina were pulled forward the septum followed the vagina; it was not held to the rectum. The close relationship of the septum to the genitourinary viscera in both sexes is of considerable importance. If a finger is introduced through a transverse perineal incision prepared for creating access to the pelvic viscera the open-

Fig. 1 Right half of pelvis of a male negro (47949, 1943) 60 years of age seen in medial view. A case in which the rectovesical pouch descended as far caudal as the middle of total length of dorsal surface of prostate gland and in which the rectovesical septum was missing.

ator may feel reasonably certain that his finger will be separated from the genitourinary organs by the rectogenital septum but will be in immediate contact with the ventral capsule of the rectum.

In Figure 6 a dorsal dissection of the pelvis of a colored female (47934, 1944) aged 35 years is illustrated. The coccyx and levator ani as well as the rectum had been removed. Both the ventral and dorsal fascial capsules of the rectum and their lateral expansions are still visible. The dorsal wall of the rectovaginal pouch and the rectovaginal septum are exposed to view. The rectovaginal septum was incised longitudinally and reflected to either side; this manipulation exposed the dorsal capsule of the vagina; upon incision and retraction of it the musculature of the vagina came into view.

By undermining the space between the septum and the vaginal capsule and the space between the rectal capsule and the septum the latter could be followed all the way down

Fig. 2 Right half of pelvis of a white male (47944, 1945) aged 60 years. Peritoneum has been removed every where except for the rectovesical pouch and septum. The hypogastric sheath is seen in its entire extent. The vas deferens passes across the superomedial surface of the superior hypogastric wing and is thus excluded from the space of Retzius. (This figure is same as Figure 6a in article entitled "Visceral Endopelvic Fascia," *Surg Gyn Obst* 94:8 86-9-28.)

to the pelvic floor its length from the line of attachment to the pouch down to the pelvic floor was 58 millimeters (as compared to 30 millimeters in the female discussed previously).

At first we were unable to see a boundary line between the septum and the dorsal peritoneum of the pouch. From outside the two looked alike but could be distinguished from the fascial sheets. Gradually as the specimen was worked on and the peritoneum and septum were pulled and stretched in different directions a faint line which gradually became more pronounced was discovered; it was crossed by a number of what appeared to be fascial strands. Even then complete certainty could not be obtained until we introduced the handle of a scalpel through an incision in the dorsal wall of the pouch; this procedure permitted exploration of the pouch and exact determination of the line along which the septum was attached to the pouch.

septum. From this level on cranially the ventral capsule of the rectum. If there was one could not be displayed gross anatomically as a layer independent of the peritoneal covering of the rectum. In connection with this condition it should be pointed out that the rectovesical septum could be distinguished clearly from the fascial capsules as will be referred to again. Its texture and color were different from those of the fascial sheets.

In Figure 4 (479, 4 1945) an extreme case of the scar at the bottom of the rectovesical pouch is illustrated (for measurements see Table II). In this subject a colored male aged 47 years, this line extended far laterally rising up cranially along the lateral wall of the pouch where on the outside a well developed lateral peritoneal wing was attached to the pouch. Its line of attachment corresponding exactly to the location of the linear scar. While elsewhere in the pouch the peritoneum showed a perfectly smooth surface it was thrown along the whitish line into many wrinkles and coarse folds running perpendicular to the line and creating the impression that some secondary processes of reorganization had taken place in this region during development. In addition a series of strong peritoneal cords had developed which were running in dorsoventral direction bridging over the line of fusion. Obviously these cords must have had the effect of re-enforcing the line of fusion preventing a secondary splitting of the septum into its two original layers. Seeing this line and its accessory formations in a specimen as the one described above one could not be in doubt that the rectovesical septum is the result of fusion of the dorsal and ventral walls of the rectovesical pouch with one another. This line corresponds exactly to the line of attachment of the septum. It is the only place in the pouch where the peritoneum is not smooth and the peritoneal structures developed along this line have the effect of preventing a re-opening of the fused portion of the pouch.

The rectovaginal septum of the female pelvis is illustrated in Figure 5 picturing the left half of the pelvis of a colored female (479a 1946) aged 39 years. In this subject however the mode of attachment of the septum to the peritoneum differed from the specimens de-

scribed previously. The peritoneum at the bottom of the pouch was carefully examined but neither the whitish "scar" nor any signs of processes of reorganization were detected. The cranial end of the septum split into two leaves, a ventral and a dorsal leaf each of these was attached separately. The ventral leaf was continued without discernible break into the ventral and dorsal wall, respectively of the rectovaginal pouch. Across the gap between the two limbs, the peritoneum of the pouch had grown as a continuous peritoneal partition separating the space of the gap from the peritoneal cavity and, at the same time re-enforcing the line of fusion in the manner of a binder. Obviously this is only a special case of the peritoneal cords. Instead of cords related from one another by varying intervals the peritoneum had grown over the gap between the two leaves of the septum as a single continuous sheet.

As in the male the fascial capsules of the viscera adjacent to the septum could be displayed as structures entirely separate from the septum (Fig. 5). Moreover as in many males the ventral capsule of the rectum was attached cranially to the peritoneum of the pouch and could not be demonstrated cranial to this level, as an individual layer. As the illustration shows the same condition existed with respect to the capsule of the vagina beyond the level of its attachment to the peritoneum of the pouch over the body and fundus of the uterus no individual capsule could be demonstrated a condition which however is well known.

We observed in this specimen before a dissection was made that the rectovaginal septum passed from its cranial attachment forward to the dorsal wall of the vagina to which it was closely adherent while dorsally it was separated from the rectum by a considerable space filled with loose connective tissue. When the uterus and with it the vagina were pulled forward the septum followed the vagina. It was not held to the rectum. This close relationship of the septum to the genitourinary viscera in both sexes is of considerable importance. If a finger is introduced through a transverse perineal incision prepared by creating access to the pelvic viscera the rect-

septum. From this level on cranially the ventral capsule of the rectum. If there was one could not be displayed gross anatomically as a layer independent of the peritoneal covering of the rectum. In connection with this condition it should be pointed out that the rectovesical septum could be distinguished clearly from the fascial capsules as will be referred to again. Its texture and color were different from those of the fascial sheets.

In Figure 4 (479 & 1045) an extreme case of the "scar" at the bottom of the rectovesical pouch is illustrated (for measurements see Table II). In this subject a colored male aged 47 years this line extended far laterally rising up cranially along the lateral wall of the pouch where on the outside a well developed lateral peritoneal wing was attached to the pouch its line of attachment corresponding exactly to the location of the linear "scar". While elsewhere in the pouch the peritoneum showed a perfectly smooth surface it was thrown along the whitish line into many wrinkles and coarse folds running perpendicular to the line and creating the impression that some secondary processes of reorganization had taken place in this region during development. In addition a series of strong peritoneal cords had developed which were running in dorsoventral direction bridging over the line of fusion. Obviously these cords must have had the effect of re-enforcing the line of fusion preventing a secondary splitting of the septum into its two original layers. Seeing this line and its accessory formations in a specimen as the one described above one would not be in doubt that the rectovesical septum is the result of fusion of the dorsal and ventral walls of the rectovesical pouch with one another. This line corresponds exactly to the line of attachment of the septum. It is the only place in the pouch where the peritoneum is not smooth and the peritoneal structures developed along this line have the effect of preventing a re-opening of the fused portion of the pouch.

The rectovaginal septum of the female pelvis is illustrated in Figure 5 picturing the left half of the pelvis of a colored female (4,90 1046) aged 29 years. In this subject however the mode of attachment of the septum to the peritoneum differed from the specimens de-

scribed previously. The peritoneum at the bottom of the pouch was carefully examined but neither the whitish "scar" nor any signs of processes of reorganization were detected. The cranial end of the septum split into two leaves a ventral and a dorsal leaf each of these was attached separately and was continued without discernible break into the ventral and dorsal wall, respectively of the rectovaginal pouch. Across the gap between the two limbs the peritoneum of the pouch had grown as a continuous peritoneal partition separating the space of the gap in the peritoneal cavity and at the same time re-enforcing the line of fusion in the same a binder. Obviously this is only a special case of the peritoneal cords. Instead of cords isolated from one another by varying intervals the peritoneum had grown over the gap between the two leaves of the septum as one single continuous sheet.

As in the male the fascial capsules of the viscera adjacent to the septum could be displayed as structures entirely separate from the septum (Fig. 5). Moreover as in the males, the ventral capsule of the rectum was attached cranially to the peritoneum of the pouch and could not be demonstrated cranial to this level as an individual layer. As the illustration shows, the same condition existed with respect to the capsule of the vagina beyond the level of its attachment to the peritoneum of the pouch over the body and fundus of the uterus no individual capsule could be demonstrated a condition which however is well known.

We observed in this specimen before a dissection was made that the rectovaginal septum passed from its cranial attachment forward to the dorsal wall of the vagina which it was closely adherent while dorsally it was separated from the rectum by a considerable space filled so with loose connective tissue. When the uterus and with it the vagina were pulled forward, the septum followed the vagina. It was not held to the rectum. The close relationship of the septum to the genitourinary viscera in both sexes is of considerable importance. If a finger is introduced through a transverse perineal incision, preparatory to creating access to the pelvic viscera the

to the pelvic floor; its length from the line of attachment to the pouch down to the pelvic floor was 58 millimeters (as compared to 30 millimeters in the female discussed previously).

At first we were unable to see a boundary line between the septum and the dorsal peritoneum of the pouch. From outside the two looked alike but could be distinguished from the fascial sheets. Gradually as the specimen was worked on and the peritoneum and septum were pulled and stretched in different directions, a faint line which gradually became more pronounced was discovered; it was crossed by a number of what appeared to be fascial strands. Even then complete certainty could not be obtained until we introduced the handle of a scalpel through an incision in the dorsal wall of the pouch; this procedure permitted exploration of the pouch and exact determination of the line along which the septum was attached to the pouch.

Exactly as inspection of midsagittal sections, complete dissection from the dorsal side

Fig. 4. Right half of the pelvis of male seen from the medial view. Not the line of transverse crease in the bottom of the rectovaginal pouch and several wrinkles in the peritoneum, running perpendicular to the line. Others that the fascial capsule of the rectum and that of the bladder and prostate are practically independent of the rectovesical septum. (Illustrated by J. H. L. M. M.)

lead to the conclusion that the rectovaginal septum is a structure of real existence that it is continuous with the peritoneum of the rectovaginal pouch but is entirely independent and different from the fascial capsules of the adjacent pelvic viscera.

3. *Eccentricities of the rectovaginal septum*
The cases of rectovaginal septum discussed in the preceding paragraphs were especially selected because they are among those which have a bearing on the developmental origin of the septum. Many similar examples have been found over a period of many years in the student dissecting room and in special dissections. These cases, however, do not convey an idea of the great variability of the septum with respect to its completeness. It has already been mentioned that in rare cases the septum may be entirely missing. But there are instances in which the septum is perforated by holes in a varying degree and other instances in which it no longer impresses a

Fig. 4. Right half of pelvis of male seen from the medial view. Not the line of transverse crease across the bottom of the rectovaginal pouch, others the fold and lines of the peritoneum along the sac and peritoneal coat behind it.

sheet but consists of a number of separate narrow strips which become very thin caudally and fade away on the bladder, prostate gland or vagina. This variability in completeness explains some of the differences of description found in the literature as well as the failure of some authors to find such a septum.

Nevertheless if a well developed septum is present it can be easily distinguished by gross examination from the surrounding fascial sheets. The fascial sheets of the visceral capsules while they represent definite membranous envelopes nevertheless evoke upon touch the feeling of a more loosely woven material of felt like nature. The surfaces of these capsules are rough, of whitish color and of irregular appearance. The septum on the contrary does not feel fibrous; it feels to the touch like a smooth and firm, densely woven material. Moreover in many cadavers the surface of the septum has a distinct tinge of pinkish bluish tint. In several instances the septum stood out prominently as a faint but bluish greenish color similar to that of the bladder, however, we are uncertain concerning the source of this pigment.

In the male cadaver 47941 1945 (illustrated in Fig 2) the pouch, together with the cranial half of the septum, was removed placed in alcohol and examined later under a binocular dissecting scope. The outer surface of the septum and of the peritoneum of the pouch was covered by a thin layer of brownish colored areolar tissue of loose texture through which the peritoneum and septum could be seen in many places. After this outer layer had been removed, the surface of the remaining parts appeared slightly bluish to the naked eye. The septum consisted of coarse flat ribbon like fibers of considerable width and of a bluish and glistening surface they were wrinkled cross-wise as if they had shrunk by retraction of some elastic material within them. All of these fibers were running in cranio-caudal direction (from the pouch toward the pelvic floor) and were arranged in two layers easily separable from one another. The fibers of each layer were continued upon the outer surface of the corresponding wall of the pouch, where they gradually faded away in the peritoneum. Close to the bottom of the pouch these fibers were more densely placed than farther caudally many of them however extended through the whole length of the septum as far caudal as the cut edge of the septum where they were cut off. The spaces between the fibers were filled in by a delicate and transparent loose connective tissue.

In many instances the rectogenital septum may be easily and neatly split into a dorsal and a ventral leaf. Thus we have demonstrated to our students for many years and we advise them routinely to attempt a separation of the septum into its two original layers. Pelvis that have been halved by a midsagittal section are especially suitable for this purpose. Running the handle of a scalpel repeatedly along the white line on the inner surface of the pouch and exerting at the same time cautious pressure will frequently accomplish the desired result. In cases of the presence of peritoneal cords bridging over the scar these cords must be carefully cut through. In the dorsal dissection illustrated in Figure 6 an attempt to split the septum was made and succeeded very easily.

Fig 5 Part of left half of pelvis of colored female, picturing rectovaginal septum and its relationship to capsules of rectum and vagina. Peritoneum left intact. (This is same as Figure 2 in article entitled "Visceral Endopelvic Fascia" *Surg Gyn Obst* 1948, 86 9-28.)

It seems that under certain conditions splitting of the septum and reopening of the pouch can occur in life. In this connection a report published by J M H Rowland in 1926 on a case of extrauterine pregnancy is of interest. The embryo developed entirely in the peritoneal cavity dorsal to the uterus. At term the head of the child which was delivered by cesarean section was found in the pouch of Douglas where it had moved all the way down to the floor of the pelvis. No break in the peritoneal lining of the pouch was found. The weight of the fetus evidently had split and separated the two layers of the septum thus reopening the pouch to its original caudal extent.

OBSERVATIONS IN INFANTS

Of the infants which we examined 37 will form the subject of this article.

Only in a single one (dissection 48 1946 colored female Infant full term dissected by Dr R M Cunningham) of these 37 infants did the rectogenital pouch extend all the way down to the pelvic floor. It was dissected from the dorsal side after removal of the sacrum coccyx and rectum together with the dorsal

Fig 6 Dorsal dissection of pelvis of colored female (4799, 1943) aged 35 years. Coccyx, levator ani, and rectum have been removed. Dorsal and ventral leaves of fascial capsule of rectum were incised longitudinally. On the left side they are shown cut away; on the right side they are reflected to the right. The rectovaginal septum is seen from its dorsal aspect through longitudinal slit in the capsule and muscular wall of the vagina are visible.

wall of the rectovaginal pouch, the ventral wall of the pouch was exposed in a dorsal view (Fig 7). The peritoneum is seen to cover the entire dorsal wall of the vagina from which it is reflected at the level of the pelvic floor. While this infant does not represent an early fetal stage (it is a full term baby) it is noteworthy that we have never encountered this condition in adult cadavers.

Of the remaining 36 infants which are recorded in Tables III and IV we made measurements to ascertain the level of the bottom of the pouch in relation to certain landmarks. In both sexes—there were 20 males and 16 females—four measurements were taken from each specimen. The landmarks which were used as measuring points, are shown diagrammatically in Figures 8 and 9.

In not one of the 36 recorded infants did the peritoneal pouch extend to the floor of the pelvis although the youngest among them were only 6 months intrauterine age and with few exceptions, a rectogenital septum was already present resembling the rectogenital septum of the adult. In Figure 10 (4799, 1943) a sagittal section through the pelvis of a representative case is illustrated. The rectovaginal pouch is seen as well as the rectovaginal septum which was continued uninterrupted into the peritoneum at the bottom of the pouch. In Figure 11 (4799, 1943) a sagittal section through the pelvis of a male infant is illustrated, in which no septum was present. From the ventral wall of the rectovaginal pouch a hollow spur was projecting in caudal direction. It is possible that this was the beginning of the proc-

esses leading ultimately to the formation of the septum. This infant, however, did not represent a particularly early stage; its intrauterine age was 7 8 months and its crown-rump length 26.5 centimeters. The bottom of the pouch extended unusually far caudally; it was situated below the level of the caudal end of the prostate gland. As has been mentioned, there are few adults in which the septum is missing (Fig. 1).

In Figure 12 a midsagittal section through the pelvis of a male infant (479²⁸ 1943) is diagrammatically illustrated among the 20 male infants recorded in Table III; it was one of the two in which the rectovesical pouch extended closest to the ventral commissure of the anus, the other one being 479²⁸. Neither of these two infants was among the earliest stages; one of them (No. 30) was 7.5 months, the other one 7.8 months intrauterine age.

In Figure 13 (479²⁸ 1943) a similar sketch is presented of the pelvis of a female infant in which the rectovaginal pouch extended farther caudally than in any of the other female infants recorded in Table IV; again it was not one of the youngest female infants (8.1 months intrauterine age as against 6 months in the youngest infant).

The variation of the value expressing distance of the bottom of the rectogenital pouch from the anus is very considerable, and since as mentioned (Tables I and II) there is also great variability of this value in the adult, it is very difficult to feel certain as to the sig-

Fig. 7. Pelvis of a female infant (dissection 48, 1930) colored, born at term, seen in a dorsal view after the sacrum, coccyx and rectum had been removed. The dorsal wall of the vagina, incised longitudinally, is seen. It is covered in its full length with peritoneum. The rectovaginal pouch extended fully to the floor of the pelvis.

nificance of these variations in the infant. Attention should be called, however, to the fact that in a general way the pouch of both sexes extended farther caudally in infants born one or several months before term than in those which were born close to or at term.

But there is another line of evidence which suggests rather forcefully that a retraction of the rectogenital pouch in both sexes does take

Fig. 8. Diagrammatic midsagittal section through pelvis of male infant, showing landmarks which were used in four routine measurements. I Distance of bottom of rectovesical pouch, cranial to ventral commissure of anus. II Distance of bottom of rectovesical pouch cranial to apex of prostate gland. III Distance of bottom of rectovesical pouch, caudal to base of prostate gland. IV Length of dorsal surface of prostate gland.

Fig. 9. Diagrammatic midsagittal section through pelvis of female infant, showing landmarks which were used in four routine measurements. I Distance of bottom of rectovaginal pouch, cranial to ventral commissure of anus. II Distance of bottom of rectovaginal pouch, caudal to dorsal fornix of vagina. III Distance between dorsal fornix of vagina and dorsal commissure of opening of vagina (length of vagina). IV Distance between dorsal fornix of vagina and external orifice of cervix (length of intravaginal portion of cervix).

at least in some cases, even after birth. It has been stated in the adult male the rectovesical pouch extends rarely below the level of the cranial end of the prostate gland and in the adult female only a narrow strip along the cranial end of the dorsal vaginal wall is covered with peritoneum.

But in infants ranging from 6 months intra-uterine age to full term (Tables III and IV), large portions of both prostate gland and dorsal vaginal wall may be covered by the peritoneum of the rectogenital pouch. In the male infants the bottom of the rectovesical pouch was located only in a single case cranial to the base of the prostate gland, and this was one of the older infants (8 5 months of intra-uterine age). In the other 19 cases the pouch

TABLE III—DEPTH OF RECTOVESICAL POUCH IN MALE INFANTS (in mm.)

Series 479a-m 943

(For method of measurement see Fig. 3)

Fig. 11. Left half of the pelvis of male infant (4790, 1043) of 7.8 months' intrauterine age. Rectovesical pouch descends as far caudal as to the level of caudal end of prostate gland. Instead of a rectovesical septum a hollow spur projects caudally from the ventral wall of rectovesical pouch. For measurements see Table I. A Rectovesical pouch, B peritoneum, C intestinal canal, D longitudinal musculature of rectum, E internal sphincter of anus, F external anal sphincter, G bladder, H prostate gland, I pubococcygeus muscle, A central perineal body, L symphysis pubis, M bulb of urethra, N bulbocavernosus muscle.

extended caudally to a level corresponding to 15—100 per cent of total length of dorsal surface of the prostate gland in 3 of these cases the bottom of the rectovesical pouch was located even caudal to the lower end of the prostate gland. In the 16 female infants recorded in Table IV 19—57 per cent of total length of dorsal vaginal wall was covered with peritoneum and in 1 female infant illustrated in Figure 7 the entire length of the vagina was covered with the peritoneum of the ventral wall of the rectovaginal pouch.

Moreover the measurements suggest that during late intrauterine life the process of fusion of the dorsal with the ventral wall of the rectovaginal pouch is constantly in progress. In the male infants the average distance of the prostate covered with peritoneum at the intrauterine ages from 6.5 to 7.8 months was 71 per cent of the total length of the prostate while in male infants ranging from 8 months to full term only 33 per cent of the total length of the prostate was covered with peritoneum. This means that during the last month of pregnancy the rectovesical pouch receded far over half the distance of the pros-

Fig. 12. Diagrammatic mid-sagittal section through pelvis of a male infant (4790, 1043) of 7.5 months' intrauterine age. The bottom of the rectovesical pouch extended caudally 2 millimeters below the apex of the prostate gland. The entire dorsal surface of prostate gland was covered by peritoneum.

tate gland which it covered during the preceding 1½ months.

In the female this process of retraction is not so pronounced. In infants ranging from 6 to 7.8 months intrauterine age the cranial 32 per cent of the vagina is covered with peritoneum while in infants ranging from 8.1 months to full term the part of the dorsal vaginal wall covered by peritoneum amounted to 29 per cent of the total length of the vagina. For some unknown reason the progress of retraction in the female is retarded at an earlier age than in the male infant resulting in the well known fact that in adult females the bot-

Fig. 13. Diagrammatic mid-sagittal section through pelvis of a female infant (4790, 1043) of 8.1 months' intrauterine age. The bottom of the rectovaginal pouch lies far below the level of the external orifice of cervix. 39 per cent of the total length of the vagina is covered with peritoneum.

Fig. 4 Dorsal dissection of negro female infant (479, 1943) born term. The fascial capsules of the rectum and vagina, and the rectovaginal septum are shown as independent structures. The dorsal capsule of rectum was slit open longitudinally and reflected. The rectum was cut through transversely and its stumps reflected. The ventral capsule of rectum was slit open and retracted laterally; on the left side it was left (attached to the bottom of the rectovaginal pouch, on the right side its cranial end) as separated from peritoneum of rectovaginal pouch and reflected caudally. The rectovaginal septum is seen in the space between retracted parts of ventral capsule of rectum. In the slit of the incised septum is seen the dorsal capsule of vagina and through a slit in it the muscle layer of the dorsal wall of the vagina.

tom of the pouch in general lies closer to the pelvic floor than in adult males.

In the female infant (among other infants) illustrated in Figure 10 the rectovaginal septum was carefully examined and dissected in its median portion. For a distance of 27 millimeters of its longitudinal extent it could be clearly displayed. Its cranial end was firmly attached to the bottom of the rectovaginal pouch into the peritoneum of which it continued without any perceptible boundaries. The most caudal portion of the septum (beyond the extent of 27 mm) could not be clearly displayed; it seemed to broaden out (in dorsoventral direction) due to the inclusion of fibrous tissue both ventrally and dorsally. Some of the fibers seemed to be muscle fibers. The septum was anchored by this thickened portion into the pelvic floor just cranial to the

sphincter and externus. By gentle pressure, with a flat and blunt instrument, against the bottom of the rectovaginal pouch, the septum could easily be separated into a dorsal and a ventral leaf corresponding to the fused walls of the pouch.

One feature which is most conspicuous in the adult could be clearly demonstrated already in these early stages. In both sexes there is only some loose cellular tissue located in the space between the rectum and the rectovaginal septum. Ventrally on the contrary the septum is closely adherent to the prostate gland in the male infants and to the dorsal wall of the vagina in the female infants.

In Figure 14 a dorsal dissection of the pelvis of a female infant (479, 1943) is illustrated. The sacrum had been removed; the dorsal fascial capsule of the rectum was split open longitudinally and reflected; the rectum was cut through and its stumps reflected. The ventral capsule of the rectum was carefully incised longitudinally and retracted to either side. The rectovaginal septum was slit open and the capsule on the dorsal wall of the vagina was exposed through the slit of the retracted sides of the septum. The vaginal capsule was then incised and the muscle layer of the dorsal vaginal wall came into view. Throughout the dissection it was quite easy to differentiate between the peritoneum and the fascial components. But it was impossible to distinguish the rectovaginal septum from the peritoneum of the rectovaginal pouch. There was no boundary between the two structures; the transition of the peritoneum of the dorsal wall of the pouch into the septum was imperceptible. By palpation with the fingers, guided by previous experiences, the approximate extent of the pouch was ascertained and an incision was made about 1 centimeter above the level at which the pouch was believed to end. A blunt probe was then inserted through the opening and the caudal boundaries of the pouch were determined as shown in Figure 14. All these observations were checked and verified by further dissection after the drawing had been made.

As in the specimen illustrated in Figure 7 an attempt was made to reopen the fused

part of the pouch by cautious pressure exerted upon the bottom of the pouch the line of fusion was easily opened and the septum split into its ventral and dorsal leaves.

Another important observation was made in this specimen. The dorsal capsule of the rectum could be displayed easily along the entire length of the gut. The ventral capsule on the contrary became fused to the dorsal wall of the pouch and could not be displayed farther cranially as a layer independent of the peritoneum. As stated previously the same situation exists in many adult subjects.

SUMMARY

1 In the subperitoneal space which separates the rectum from the urogenital organs a transverse membranous septum the rectovesical septum in the male the rectovaginal septum in the female, is present which is attached cranially to the peritoneum at the bottom of the rectogenital pouch and caudally

to the dorsal surface of the prostate in the male to the dorsal surface of the vagina in the female. In some cases it may extend as far caudal as the pelvic floor.

2 Two views concerning the nature of this septum are in existence. According to one of them the septum is the result of a fusion in earlier intrauterine life of the dorsal with the ventral wall of the rectogenital pouch which originally extends as far caudal as the pelvic floor. According to the other view the septum is not of peritoneal origin but is purely of fascial origin. There is a third group of investigators who have not been able to demonstrate this septum in the female but claim that the tissue between rectum and vagina consists merely of the fascial capsules of these two organs and some loose areolar tissue in between them.

A. Observations in adults. 1 With few exceptions the rectogenital septum can be clearly demonstrated in the adult pelvis of

both men and women either in midsagittal sections through the pelvis or in dissections of the pelvis from the dorsal side. While there are subjects in which the septum is missing and others in which it is perforated or consists only of separate strips, it represents most often a firm transverse membranous partition between rectum and urogenital organs, attached cranially to the peritoneum of the pouch caudally to the urogenital organs.

2 In most instances the septum can be demonstrated as an individual structure additional to and independent of the fascial capsules of the adjacent viscera.

3 There is, however a constant difference in the relation of the septum to the capsules of the rectum and urogenital organs. From the capsule of the rectum the septum is separated by ample yet easily broken down loose areolar tissue but adheres closely to the capsules of bladder seminal vesicles, and prostate in the male and to the capsule of the vagina in the female. In creating perineal access to the space between rectum and urogenital organs the septum invariably comes to lie ventral to the finger separating the finger from the prostate or vagina.

4 When seen from outside or in sagittal sections, the rectogenital septum is continued without any visible boundary into the peritoneum of the rectogenital pouch.

5 Its surface texture is entirely different from that of adjacent fascial membranes. While the latter present a dull, whitish and felt like surface, the surface of the septum is glistening evenly membranous, of firm texture and sometimes of faintly greenish color.

6 The peritoneum of the pouch, when inspected on its inner surface, presents along the line along which the septum is attached to its outside, features which make this line most conspicuous as compared to the smooth, even surface of the remainder of the peritoneum of the pouch.

The attachment of the septum is marked by a simple whitish line which resembles a scar and may be slightly grooved. In some cases slight wrinkles running perpendicular to this line, may be seen in the peritoneum on either side of the line. In extreme cases the peritoneum is thrown into marked folds per-

pendicular to the line and strong peritoneal cords are developed bridging across the line, evidently as safeguards against splitting the septum and reopening the fused part of the pouch. The obvious interpretation of these features is that the white, scar-like line on the inner surface of the peritoneum of the pouch is the line along which the dorsal and ventral wall of the pouch have fused with one another and that in some cases special structures, such as the peritoneal cords, have developed to prevent a reopening of the closed portion of the pouch.

7 In accordance with these views is the fact, that application of cautious pressure along the white line will easily split the septum into its original dorsal and ventral leaves.

B Observations in infants 1 With exception of a single female full term infant in which the rectovaginal pouch still extended down to the pelvic floor in 36 male and female infants, varying from 6 months intramutuum to full term the rectogenital pouch of the peritoneal cavity had already started to retract from out of the rectogenital space and the rectogenital septum was developed.

2 As in adults, the rectogenital septum of infants is clearly differentiated as an individual membranous structure, independent of the fascial capsules of the adjacent pelvic viscera.

3 Relative to the prostate in the male and to the vagina in the female however the rectogenital pouch in the infant descends to a more caudal level than it does in adults therefore larger portions of both prostate and vagina are covered by the peritoneum of ventral wall of pouch in infants than in adults.

4 The extent to which the prostate and vagina are covered by peritoneum diminishes distinctly during the last months of intra uterine life, indicating that further retraction of the pouch is in progress during this period.

5 As in adults the tissue of the rectogenital septum is continued without perceptible boundary into the peritoneum of the rectogenital pouch. When viewed from outside it cannot be distinguished from the peritoneum of the pouch but is well differentiated from adjacent fascial tissues.

6 Applying slight pressure to the bottom of the rectogenital pouch, one succeeds easily

in splitting the septum into a dorsal and ventral leaf, corresponding to the dorsal and ventral walls of the pouch, through fusion of which with one another the septum has formed during earlier stages of development

CONCLUSIONS

Considering all the evidence presented in this article the authors conclude that the rectogenital septum as shown for the first time by Cunéo and Veau is of peritoneal origin and the result of a fusion of the dor-

sal with the ventral wall of the rectogenital pouch

THE EFFECT OF SURGICAL INTERRUPTION OF THE GASTRIC BLOOD FLOW UPON GASTRIC SECRETION AND THE PREVENTION OF EXPERIMENTAL PEPTIC ULCERS

HARRY H. LEVEEN, M.D., M.S., New York, New York

CONSIDERATION of energy metabolism of the secreting parietal gland has shown that active secretion utilizes oxygen and glucose that the secretory pressure attains heights greater than the blood pressure indicating that the secretion is not simply an ultra filtrate of plasma, that augmentation of vascularity occurs concomitantly with secretion. It has been known for some time that an increase in vascularity is a prerequisite for glandular secretion (11).

Gray has computed the energy requirement for 1,000 cubic centimeters of active gastric parietal cell secretion to be about 1.5 calories which could be furnished by the oxidation of 5 grams of glucose. If 25 milligrams of glucose were removed from every 100 cubic centimeters of blood 168 cubic centimeters of blood per minute would have to circulate through the stomach to sustain a parietal secretion of 1,000 cubic centimeters per hour. Richards and coworkers have demonstrated a marked increase in the vascularity of the stomach during active secretion; others have found an increase of 30 to 40 per cent in cardiac output during active digestion. The energy requirements for active gastric secretion are satisfied by additional gastric blood flow.

Somervell employed ligation of gastric vessels as a mode of therapy in patients with peptic ulcer. He demonstrated reduction in free hydrochloric acid output following these ligations. The experiments of Layne and Bergh on dogs seemingly invalidate these clinical claims. Their animals did not survive ligation of all the major gastric vessels and ligations of lesser magnitude effected no change

in the acidity of histamine stimulated gastric juice.

Hay and associates have shown that injection of histamine in beeswax is productive of typical peptic ulcers in laboratory animals. Lannin has used histamine in beeswax to test the value of various types of gastrectomies in dogs. The failure to develop peptic ulcers after histamine in beeswax injections would critically test the value of gastric artery ligation as a form of therapy for peptic ulcer. As yet there has been no adequate experimental confirmation to indicate that the utilization of the ligation procedure would produce worthwhile results.

EXPERIMENTAL

The major gastric arteries of dogs were ligated under general anesthesia. The left and right gastropiploic arteries and vasa brevia were ligated and divided. The right gastric vessel is small and inconstant in the dog but when it could be identified it was likewise ligated.

The surviving dogs were kept for periods of 1½ to 3 months and then given daily intramuscular injections of 30 milligrams of histamine in beeswax. The dogs were sacrificed on the 15th day. Normal dogs were used as control animals for the histamine in beeswax injections.

The gastric secretory responses were studied with regard to volume and acidity in 4 dogs surviving 1½ months or longer.

RESULTS

Thirty dogs were subjected to gastric ligations. Of this group 16 died before injections of histamine and beeswax were started. In these 16 dogs the stomach showed a diffuse area

Approximate values as determined by test papers

On occasion (not included in the average) no free acid was obtained and pH was in the region of 4

On occasion (not included in the average) no juice as obtained and stomach washings with distilled water contained no free acid

of infection in 4. In 4 others perforated ulcers were seen on the greater curvature adjacent to the spleen. In 2 dogs a nonperforated gastric ulcer was seen adjacent to the spleen on the greater curvature of the stomach. In 6 dogs the stomach was normal, death being due to other causes.

Fourteen dogs survived a period of 1½ to 3 months; these dogs were injected intramuscularly with 30 milligrams of histamine in beeswax daily for a period of 14 days and sacrificed on the 15th day. Four of these dogs died before completion of the injections. Of these 2 had large perforated ulcers high on the greater curvature adjacent to the spleen. One dog died of other causes but was found to have a chronic penetrating ulcer in a similar position. The ulcers were similar in appearance, position, and shape to those seen in dogs in which ulcers had developed following vascular ligation alone. One dog had occasional very shallow pinhead sized erosions in the prepyloric area. The remaining 10 dogs were sacrificed on the 15th day and were subjected to postmortem examinations. Of these dogs one showed occasional pinhead sized superficial erosions in the antrum. The 9 other dogs showed no evidence of ulceration upon examination.

Ten normal control dogs were given daily intramuscular injections of 30 milligrams of histamine in beeswax and were sacrificed on the 15th day. Four dogs had typical duodenal peptic ulcers and 1 dog had a typical prepyloric peptic ulcer on the lesser curvature. Of the remaining 5 dogs 2 showed small duodenal erosions and 2 showed hemorrhagic

duodenitis or gastritis. Although only half of the dogs developed typical peptic ulcers, in none was the stomach or duodenum found to be normal.

In 4 dogs the secretory responses to aqueous histamine (1 mgm.) were studied in the fasting state before and after ligation. This was accomplished by passing a tube through the mouth into the stomach. The stomach was emptied of its contents by aspiration immediately before the administration of histamine and 1 hour later. The pH of the aspirated contents was obtained by means of a glass electrode. The free and total acids were determined with Topfer's reagent and phenolphthalein. If the fasting contents contained free acid the test was discontinued and repeated on another day. The average of the 3 most optimum responses of 6 or more tests are tabulated in Table I. As a rule gastric ligation did not affect the values for pH and free and total acid in the optimum responses but the volume of secretion was markedly reduced. The results are in accord with those of Layne and Bergh who did not, however, study secretory volume changes. Following ligation the secretion was so scant that, on many occasions, it was often necessary to wash out the stomach with distilled water in order to determine the presence of free acid. Often histamine failed to evoke a secretory response after ligation or the juice was low in free acid and of relatively low hydrogen ion concentration (pH).

The response to insulin was likewise tested and was found to be such a weak stimulus that consistent results were not obtained prior to

ligation. As a rule the free acid rarely rose above 50 units before ligation and little response was obtained with a comparable dose after ligation.

MICROSCOPIC EXAMINATION OF ULCERS PRODUCED

Those ulcers which appeared in the control dogs (without vascular ligations) were typical peptic ulcers, the description of which is so well known that only brief mention will be made of the changes for purposes of contrast. These ulcers all had sharply demarcated margins with overhanging edges of viable mucosa. As a rule the following zones could be made out in the ulcer: a zone of necrosis, a zone of fresh granulation infiltrated with inflammatory cells, and a zone of fibroplasia (beginning scar tissue formation) at the base. The viability of the mucosa adjacent to the ulcer was unimpaired.

All the ulcers appearing in those dogs which had ligations of their gastric vessels differed from the true peptic ulcers described. Mucosal coagulation necrosis (or the earlier cellular changes of this process) adjacent to the area of ulceration was always found. In those dogs dying with infarction the necrosis was more widespread but still more pronounced in the mucosa. The inflammatory reaction and the zone of viable granulation tissue were much less prominent in this group of ulcers and frequently absent. The microscopic findings for the reasons enumerated failed to illustrate a punched out area of ulceration but rather presented an area of superficial necrosis which became deeper as the center of the ulcer was reached.

Briefly, the true peptic ulcers show lytic necrosis produced by digestion of living tissue. The ulcers of vessel ligation show coagulation necrosis with secondary digestion and the tissue response which is dependent upon blood supply is less pronounced.

DISCUSSION

Cutting and associates studied the volume and acidity of gastric secretion in cats together with simultaneous volumetric measurements of venous return from the stomach. They found the volume of acid secretion after histamine

stimulation, to be directly proportional to the rate of blood flow. When the rate of gastric blood flow after histamine stimulation was altered by physical means or vasomotor drugs, a corresponding change occurred in the secretory volume. They conclusively proved that with an augmented rate of secretion as increased blood flow occurs and that any factor which prevents this increase in blood flow will likewise restrict the secretory response. All our experimental findings are in complete accord with the findings of Cutting and his co-workers.

Whether the ligation of vessels would be a practical method of reducing gastric secretion and whether this reduction would be sufficient to prevent or cure peptic ulcers is a matter of conjecture.

That the human stomach can be almost completely deprived of its blood supply and yet remain viable has been adequately demonstrated in the operative attack on carcinoma of the esophagus. In this procedure the stomach is drawn into the chest cavity and anastomosed to the distal cut end of the esophagus. The failure to develop vascular ulcers and infarctions in most of the dogs operated upon further illustrates the extent to which the stomach may be deprived of its vascular supply. Other reports (8) to the contrary, notwithstanding. It became apparent early in the course of the experiment that if the stomach were not handled with extreme gentleness ulcer or infarction would occur. In the last 12 dogs on which ligations were performed, no not only did infarction or perforated gastric ulcers develop.

It may well be that those dogs operated upon in the histamine treated group which had gastric ulcers had them prior to the injection of histamine in beeswax. Microscopically the maturity and the density of fibrosis tended to confirm this impression. Also the ulcers developing from ligation alone were high on the greater curvature adjacent to the spleen. The ulcers which developed after histamine in the ligated group were in an identical position and similar in type. The microscopic pathology previously discussed was characteristic of vascular ulcers and unlike true peptic ulcer. One must therefore conclude that the ulcers devel-

oping in the ligated group were on a vascular basis. In sharp contrast ulcers developing in the histamine treated controls were typical duodenal and prepyloric peptic ulcers. Ligation of the major gastric vessels had protected against the development of "typical" peptic ulcers, and in addition, had protected against associated ulcer pathology such as hemorrhagic gastritis or duodenitis and duodenal erosions.

It is possible that the beneficial effects of vagotomy may be produced by a reduction in blood flow caused by section of the vasodilator nerve fibers to the blood vessels of the stomach. Section of the vasoconstrictor or sympathetic nerve fibers to the stomach is frequently productive of typical peptic ulcers (1). A concept of the secretory mechanism as proposed by Mathews, was that the production of secretion was effected by an increase in blood flow. The autonomic nerves serve as regulators of the blood flow. Such a concept is an oversimplification since it disregards the qualitative changes in secretion resulting from either sympathetic or parasympathetic stimulation. Nevertheless it seems that the alteration in blood flow which is produced by such nervous stimulation is the factor of major importance. More recently, Wolf has shown that a striking decrease in gastric blood flow takes place after the performance of vagotomy in humans.

That protection by ligation occurs without alteration in the pH of the optimum histamine response may seem incongruous. An all or none law for parietal cell secretion has been adequately proved (1). The parietal cell either secretes hydrochloric acid at a fixed acidity or does not secrete at all. Alterations in pH and free and combined acid result from partial neutralization of this hydrochloric acid by other alkaline components of secretion (5, 10). Histamine stimulates almost exclusively the acid components of secretion. Since the pH of histamine stimulated juice is unchanged by vascular interruption those cells which are able to secrete do so in the all or none fashion at a fixed pH.

However a reduction in blood flow does not make allowance for the satisfaction of the energy requirements of rapid secretion and the

volume of free acid secretion is reduced. This reduction in the total amount of free acid is sufficient to protect against ulceration; the duodenum is able to neutralize small quantities of hydrochloric acid effectively. The importance of the volume of acid pepsin in the production of ulcers has been established in a previous publication (9). It is of importance to point out that although optimum responses were unchanged qualitatively in the ligated group the dogs (except No. 440 in Table I) did not respond in more than half of the instances to histamine stimulation and remained achlorhydric or had scant secretion of low acidity. Since these same dogs responded well prior to ligation, one must assume that the ligation was the factor which was responsible for the lack of response.

A reduced gastric blood flow might effectively lower the hydrogen ion concentration of the total gastric secretion by decreasing the acid component when the stimulus involves both acid and alkaline components (as in vagus stimulation). The fact that insulin stimulation (post ligation) did not markedly alter the pH of the stomach contents may be explainable on this basis.

Postmortem examination of dogs as long as 4 months after ligation of the gastric vessels did not reveal a collateral circulation comparable to the initial circulation. It is therefore reasonable to make the assumption that the effects of such extensive ligations would be permanent.

Peptic ulcer of the esophagus is most often associated with ectopic gastric mucosa and peptic ulcers are not infrequently found in the stomachs of paraesophageal hernias. Even so peptic ulcers do not form in the esophagus after the operation which has been described by Phemister for removal of carcinoma of the esophagus. This fact may be attributable to the reduction of blood flow in the stomach transplanted to the intrathoracic position. Such clinical observation would tend to support the efficacy of gastric ligation as a form of therapy for peptic ulcer.

SUMMARY AND CONCLUSIONS

Ligation of the major gastric vessels by disturbing the energy requirements for secre-

tion can effectively reduce the amount of hydrochloric acid secreted by the stomach. This reduction in acid formation is sufficient to protect dogs from development of typical peptic ulcers induced by the intramuscular injections of histamine in beeswax. With extensive ligations however there is danger from the production of vascular ulcers on the midportion of the greater curvature of the stomach. Investigative work is now being carried out to determine the extent of ligation necessary for protection which might be free from hazard of vascular ulcers. There is a possibility that the beneficial effects of vagotomy might be attributable to a reduction in gastric blood flow.

THE REPAIR OF HERNIA

With Special Application of the Principles Evolved by
Bassini, McArthur and McVay

CARL O. RICE, M.D., F.A.C.S. and J. H. STRICKLER, M.D. Minneapolis, Minnesota

SINCE man first discovered the nature of groin herniation and conceived the idea of surgical repair the archives have become replete with procedures and variations each designed to ameliorate the problem of correcting the anatomic defects and consequent mechanical failure of the supporting structures in that area of the body.

In the selection of a satisfactory herniorrhaphy one must consider certain anatomical, physiological and mechanical principles that will withstand the scrutiny of statistical studies as pertains to the end results. These principles, substantiated by experimental observation, seem to be embodied in a combination of the Bassini, the McArthur and the McVay procedures for the repair of hernia. It has seemed to the authors that this can be accomplished by utilizing the locally available aponeurosis of the external oblique as strips of suture material (McArthur) to unite the inguinal structures to Cooper's ligament (McVay) and by reinforcing the floor of the canal (Bassini) as the surgical conjoined tendon is sutured to Poupart's ligament.

THE BASSINI CONTRIBUTION TO HERNIA REPAIR

Eduard Bassini described and illustrated his method of repairing inguinal hernia as he devised it shortly prior to 1890.

The principle of his operation is to reinforce an anatomical defect by decreasing the size of the internal ring and reinforcing the floor of the inguinal ligament. This he did by suturing the three layers, namely, the internal oblique muscle, the transversus abdominis muscle and the vertical fascia of Cooper (transversalis fascia) to Poupart's ligament. He then replaced the cord and sutured the fascia of the

external oblique over, re-establishing the inguinal canal and the external ring in its normal anatomical position.

Since then many other operations have been designed to narrow the opening at the internal ring and to reinforce the floor of the inguinal canal.

MCARTHUR'S CONTRIBUTION TO HERNIA REPAIR

In 1901 L. L. McArthur of Chicago reported the use of strips of the tendinous portion of the external oblique as suture material in performing the Bassini and other popular herniorrhaphies of that time. His technique consisted essentially of splitting the external ring upward and parallel to the fibers of the external oblique as far as the muscle insertion (5 to 6 inches). The edges of the aponeurosis were then raised and a strip of fascia $\frac{1}{8}$ to $\frac{1}{4}$ inch wide was split loose from the internal flap, cut free at the upper lateral end and left attached at the lower end where the internal pillar of the external ring attaches to the pubic tubercle. If a Bassini type of repair was used, he cut a similar strip from the outer lower flap of the external oblique aponeurosis, ending in the external pillar. These strips were threaded onto a needle and secured with a tie of silk to serve as a continuous stitch. He anchored the end of this stitch by a simple knot or a through and back stitch such as a tailor uses to fix his thread. The cord was placed according to the type of procedure chosen.

McArthur determined the tensile strength of these strips to be between 11 and 24 pounds. He supported his work by dog experimentation in which he showed that the fascia healed *in situ* was not absorbed and did not slough. In his final report in 1904 he cited 93 cases without recurrence and 1 example of excised tissue from a man 1 year postoperative showing the fascia strip to be still present.

Dr. Strickler is surgical fellow from the University of Minnesota School of Medicine assigned to St. Barnabas Hospital, Minnesota.

If McArthur had lived in this generation he would have in all probability applied the use of these fascial strips to a McVay type of repair much as we have done it in accordance with the description outlined in this paper. He suggested that these fascial strips could be used in any type of hernia technique.

The principle of autogenous fascial suture was studied in 1909 by Kirschner. It remained for Gallie and LeMesurier in 1924 to complete the experimental and clinical studies and to establish fascial and aponeurotic suture as a sound, useful and generally acceptable surgical tool. They demonstrated that a transplant showed the phenomenon of inflammation for a period of 3 weeks but that no absorption, invasion or infiltration occurred and that at the end of 1 year the fascia or aponeurosis had exhibited no histologic change. They concluded that healing between fascial strips and the surrounding tissue occurred by scar formation, that avoidance of intervening areolar tissue and establishment of broad contact surfaces was an aid but that reliance was placed more upon the suture itself than upon the scar. Gallie and LeMesurier repeatedly demonstrated that their transplanted strips of woven fascia lata had in no instance stretched, contracted, or ruptured.

A transplanted patch of fascia lata was used by Singleton and Stehouwer in the repair of severe direct and ventral hernias. At reoperation of 6 patients they found no reabsorption of the patch. In situations where broad contact between patch and local tissue was impractical they too preferred fascia strips since strips did not depend upon scar tissue to maintain the repair. Haas believed that transplanted fascia lata actively participated in a strong union with the muscle to which it was sutured.

In seeking to obviate the necessity of a second operative site as in the Gallie procedure Koonts made use of preserved fascia in hernial repair. He found as did Nageotte in the case of dead tendon grafts that the preserved fascia became living by a process of repopulation by fibroblasts from the host.

Pedicled grafts of the iliotibial tract of the fascia lata have been employed by Wangensteen for repair of large inguino-femoral and

abdominal wall defects. More recently Wangensteen has shifted a patch of fascia from the lower abdomen to cover a defect in the upper abdomen and has then used his pedicle fascia lata graft to cover the dispossessed area in the lower portion of the abdomen. Burton and Ramos made use of the femoral canal through which to conduct a similar pedicle. Mattice devised the use of a flap of rectus sheath to accomplish a Cooper's ligament type of herniorrhaphy.

Neuhof cited 6 to 12 months follow-up studies of experimental fascial transplants and believed that even autogenous fascial transplants became replaced by a fibrous structure of a nature similar to the original.

In a study of comparative strengths Horley found fresh autogenous fascia lata to be superior to dead preserved fascial transplants. Studies which have been made by the aforementioned authors clearly indicate that fascial strips have been widely used particularly when the defect is so large that the ordinary means of repair seem impractical. When these facts are taken into consideration one can reasonably conclude as Payne points out, that fascial suture of the McArthur type should be a very satisfactory suture material to be used in a standard herniorrhaphy.

Burdick and Gillespie summarized the end results of 1,485 cases in which hernias had been repaired by various types of fascial suture. They felt discouraged with the high incidence of recurrence and infection which was observed with fascial sutures. They made no comparison with groups of hernias of equal severity wherein foreign material was used. Since the highest percentage of the more difficult repairs in their series fell into the fascia group it seems not justifiable to lay the blame of recurrence on the fascial suture.

Guthrie Olson and Masson analyzed the results in 2,208 patients and found a recurrence rate of 7.8 per cent with autogenous fascia as against 5.6 per cent for foreign suture material. They found that fascia was used much more frequently in severe and recurrent hernias, obese individuals, those with poor musculofascial development and in men. They felt that by giving reasonable weight to these disadvantages the small statistical difference

could be more than discounted and favor placed with fascial suture

Gallie believes that failure in many cases of fascial suture repair is due to failure to anchor adequately the end of the strips. A proper tie at the end or a wire retaining suture will prevent slipping

Burdick and Gillespie feel that the passage of a large needle through Poupart's ligament will cause tearing. Cooper's ligament is sufficiently tough to withstand the strain

THE McVAY CONTRIBUTION TO HERNIA REPAIR

The use of Cooper's (superior pubic) ligament as an anchor for the inguinal strata has become accepted as a sound surgical procedure since McVay and Anson published their anatomic investigations and suggestions for the surgical application to the repair of inguinal hernia.

Cooper first observed this structure in 1804 and some years later suggested its use in the repair of hernia. Mattson in reviewing the literature pertinent to Cooper's ligament stated that Lotheisen in 1898 and Narath before him had made use of the superior pubic ligament to repair femoral and inguinal hernias. By 1927 Babcock was using the medial part of Cooper's ligament, near the pubic tubercle as a part of the procedure in inguinal repair

Before Cooper's ligament came into general use for inguinal herniorrhaphy Moschcowitz in 1907, Seelig and Tuholske in 1914 and Dickson in 1936 described its use in femoral hernia.

From dissections of over 300 inguinal regions McVay and Anson noted that the inguinal ligament was not the normal insertion for the inguinal portion of the transversalis fascia transversus abdominis and internal oblique which are actually inserted on Cooper's ligament and the pubic pecten. They maintain that the relationship of these structures to Poupart's ligament is only one of continuity

McVay also stated that the conjoined tendon is an artefact of dissection and that the true falx or ligament of Henle is a lateral expansion of the rectus abdominis tendon of insertion on the pubic pecten. Rlenhoff like-

wise found no conjoined tendon as had been previously described. McVay and Anson also observed that the inguinal ligament is only loosely held in its convex position by surrounding fascia and is easily shelled out to become the free margin of the aponeurosis of the external oblique. They demonstrated that when the inguinal strata are sutured to Poupart's ligament a cephalad bending easily occurs which leaves the inguinal region exposed below it. It is their opinion that recurrent hernia masses appear in the stretched weakened area below the elevated inguinal ligament. It is for these reasons that McVay ignores the inguinal ligament in the procedure of his herniorrhaphy. He sutures with nonabsorbable material the inferior margin of the transversus abdominis aponeurosis and its attached transversalis fascia to Cooper's ligament starting at the pubic tubercle and extending along Cooper's ligament to the femoral vein. He states that when the internal oblique muscle is aponeurotic in nature its lower border is also included in the suture.

This bulk of tissue was designated by Bassini as the *dreihaupt*; it has been erroneously called the conjoined tendon and is commonly referred to as the surgical conjoined tendon (Fig. 1).

From observations regarding mechanical forces applied to the inguinal area Lick and Samson concluded that a hernioplasty which employs Poupart's ligament creates an abnormal trihedral upon which intra-abdominal pressure exerts a force against the hernioplasty wall about sixty-two times that exerted against the normal oblate ellipsoidal floor. They felt that the use of Cooper's instead of Poupart's ligament was of great importance because then the normal ellipsoidal contour of the inguinal region was preserved. They also noted that the maximum pressure is only a few millimeters caudad to the deep epigastric vessels at the exact point of appearance of direct inguinal hernia.

A McVay type of repair seems the best mechanical support to this area providing a barrier against an approach to the floor of the inguinal canal through which direct hernias must protrude in order that they may become evident.

Harkin and Swenson reviewed the experience with 322 hernia repairs by the McVay type procedure via a semicircular incision at the late twelfth century. They had only one recurrence. Many other surgeons have discarded the H type procedures in favor of the McVay principle.

HERNIA REPAIR SHOWS THE FOLLOWING PRINCIPLES

It has impressed us that each of these principles of hernia repair has some advantages. A procedure has been devised incorporating these principles into the repair of inguinal and femoral hernia.

General anesthesia is employed. Curare is used to obtain relaxation.

The usual skin incision is made by a slight increase in length and a downward curve in its medial one third. These variations in the skin incision give a more roomy exposure to the muscular origin of the aponeurosis of the external oblique and the insertion of the fascia in the region of the pubic tubercle and Cooper's ligament.

A triangular area of external oblique aponeurosis is dissected free of its areolar tissue. A suture is inserted into the external ring, at the level of its upper margin. The fascia is split from the point laterally to the muscle fibers. This leaves a relatively broad lateral leaf of external oblique fascia which can be dissected from the roof of the inguinal canal and tunnel back (Fig. 1).

The medial (upper) leaf of this fascia is dissected free from the underlying internal oblique muscle for about 3 centimeters so as to expose the internal oblique muscle and the upper conjoint tendon.

The hernial sac is dissected free, it is ligated and is sclerotized.

Three $\frac{1}{4}$ inch strips are then made from the upper leaf of this fascia, precautions being taken to see that the strips do not extend obliquely across the fibers lest tearing develop. The preparation of these strips of fascia constitutes McArthur's contribution to the repair of hernia.

One of these strips is detached from the pubic tubercle end and two from the muscular

Fig 2 Fascial suture 1 has been partially completed. By following it from its point of attachment near the pubic tubercle it will be observed anchoring the surgical conjoint tendon to Cooper's ligament then passing across the floor of the inguinal canal, reapproximating the transversalis fascia and also approximating the edge of the internal oblique muscle to the inguinal ligament. A sponge holds back the preperitoneal fat while this suturing is being made and is removed at this stage of the operation before snugging up the tissues as illustrated in Figure 3.

end leaving them attached at their opposite ends (Fig 1 A B C)

In order to facilitate anchorage of the strip on a small oval calibered Gallie type needle the two lateral ends when cut free are left with a $\frac{3}{8}$ inch bud of muscle attached. The strip with a free medial end is cut transversely so that it contains some cross striations of the reflected portion of the rectus sheath. The fascia strip is inserted through the eye of a Gallie type needle. This strip is then pulled through the eye so that the needle point can be passed through the fibers of the strip about 3 or 4 millimeters from its free end (see insert Fig 1). The cross fibers in the muscle bud of the two free lateral ends (Fig 1 A B) and the cross fibers of the free medial end (Fig 1 C) serve to keep the fascia from stripping off the needle when tension is applied while suturing. This threading of the needle also permits use of the full length of the fascia strips.

Cooper's (superior pubic) ligament is now exposed by cutting through the thin transver-

salis fascia which lies under the cord forming the floor of the inguinal canal (see Fig 1). If the hernia is direct in character this has been already accomplished when the sac was dissected out. Usually the pubic branch of the inferior epigastric (or sometimes spermatic artery) passes transversely across the floor of the canal lying in the deeper structures of the transversalis fascia. This vessel (Fig 1) must be isolated and tied lest annoying bleeding confuse the further dissection.

Cooper's ligament lies underneath the transversalis fascia and can be easily palpated as a hard tendinous structure. It passes obliquely downward and laterally from the pubic tubercle. This strong tendinous ligament is exposed laterally nearly to the femoral vein. A dry 2 by 2 sponge is inserted into this depth to rid the field of preperitoneal fat for protection of the femoral vein and to dissect the loose areolar tissue away from Cooper's ligament. It is left there until the stitches through Cooper's ligament have been placed. It is re-

Fig. 4. Strip A now disappears from view. Strip C has been completed. Strip B has reformed a new external ring and is closing medial end of external oblique aponeurosis.

Fig. 5. All fascial strips have been completed. B and C overlap for about 2 inches. Each has been anchored with a wire suture of No. 32 stainless steel.

The internal ring is made smaller by passing the fascial strip close to its medial margin.

The tissues which have been included in this first stitch of fascia (Fig. 2 A) are approximated as the fascial strip is snugged up and the end of the fascia strip is anchored with one tie of No. 32 stainless steel wire (Fig. 3 A). It is then cut free from the needle. This portion of the procedure completes the first two stages—that of blocking the approach to the floor of the canal by suturing the bundle of muscles and transversalis fascia to Cooper's ligament (McVay) and of suturing the edge of the surgical conjoint tendon to the inguinal ligament thereby reinforcing the floor of the canal (Bassini).

The retracted cord is then replaced into the inguinal canal over its reinforced floor and the edges of the aponeurosis of the external oblique are sutured together over the cord with the second and third running stitch of fascia (Fig. 3 C and Fig. 4 B).

This changes slightly the position of the spermatic cord in that it assumes a slightly higher position as the lateral leaf of the external oblique fascia is pulled over to meet the remaining medial leaf. This also changes the position of the external ring so that instead of

finding the pubic tubercle at its medial margin it now is found at its medial and inferior margin.

Care is taken to stagger the bite of the stitch through the fascia and inguinal ligament in order to prevent splitting of the aponeurosis.

The strip of fascia with its attachment remaining at the muscular end is used to close the lateral rent in the fascia of the external oblique (Fig. 4 C). The second and third strips of fascia overlap one another for a distance of about 2 inches (Fig. 5). The end of each strip of fascia is anchored with a wire stitch. No other foreign suture material is used.

Curare is used to promote relaxation of the muscles in order to facilitate approximation without tension.

Bleeding is adequately controlled throughout the course of the operation. The skin is closed with clips.

All patients are fitted with a wide support ing abdominal girdle which they are required to wear for 6 months after the operation. This is done as a precautionary protection against the breaking of structures during the period in which scar tissue becomes well organized and firm.

SUMMARY AND CONCLUSIONS

The use of fascia as a suture material in a standard inguinal herniorrhaphy is a sound and practical procedure. Evidence as indicated in the literature suggests that fascia sutures possess strength in themselves as well as approximating values during the period of fibrous tissue proliferation. The McArthur type of strip has the additional value of being indigenous to the area of repair.

Supporting evidence has been presented from a review of the literature showing that the use of Cooper's ligament is anatomically and mechanically correct.

A procedure has been described which employs three generally accepted principles in the repair of hernia, namely: the use of locally available fascia for suture (McArthur) to approximate the inguinal strata to Cooper's ligament (McVay) and the reinforcement of the floor of the inguinal canal (Bassini).

Rather than reserve a stronger type of repair for the recurrent hernias it seems justifiable to employ the strongest type of repair on the first occasion, thereby eliminating the need for additional repair.

At the date of this writing we have repaired 40 hernias (inguinal and femoral) by this method without complications. There have been no failures though it is yet too early (6 months) to determine the eventual end results.

REDUNDANT BLIND SEGMENTS OF INTESTINE FOLLOWING SIDE-TO-SIDE ANASTOMOSIS WITH DIVISION OF THE BOWEL

Report of 5 Cases

B MARDEN BLACK M D and CECIL G McEACHERN M D., Rochester Minnesota

AFTER the removal of a segment of bowel several methods of restoring continuity of the intestinal tract are available. Each method has many advocates and circumstances such as the anatomic characteristics of the particular segment of bowel involved or the presence of obstruction, may influence greatly the choice of method. The use of a side-to-side anastomosis after the inversion of the two cut ends is a standard safe method however the possibility of complications arising from the proximal end has long been recognized. These complications are almost invariably associated with excessive length of the proximal segment of the bowel distal to the anastomosis and they should be largely preventable by careful attention to the length of this segment. How frequently such complications develop cannot be estimated but in view of the wide spread knowledge of the hazards associated with a redundant segment we were amazed to find in the literature so few papers dealing with these complications.

Pearse using dogs showed that a blind loop of bowel distal to an anastomosis became a functionless segment of intestine if the direction of the peristalsis was away from the blind end and toward the anastomosis. However if peristalsis was toward the blind end material was carried into it and stagnated there. The occurrence of changes in the blind proximal loops depended on the length of the loops in those loops which were less than 2 feet (60 cm) in length no pathologic changes developed. Those loops 3 to 4 feet (90 to 120 cm.) in length became hugely dilated hypertrophied and filled with inspissated intestinal contents.

If perforation did not occur these long blind loops caused anorexia, lethargy, emaciation and finally death after 3 or 4 months. Excision of the blind loops if carried out in time was followed by complete recovery of the animals. Loops 5 to 6 feet (150 to 180 cm) in length represented such a large part of the total intestinal length that the majority of the animals died from inanition. Estes and Holm also using dogs confirmed the observations of Pearse that when peristalsis was toward the blind end of the bowel after division of the bowel and side-to-side anastomosis either between the ileum and colon or between segments of the small bowel the blind segments became dilated to three or four times their normal diameter. Ulcers developed frequently and subsequent perforation was not uncommon.

There are few reports of clinical cases in the literature. This may be explained in part by the fact that in the past the mortality rate associated with this type of surgery has been high particularly so in cases in which the technical aspects of the operation were not entirely satisfactory. A fact of greater importance however is that probably excessively long loops are not left usually and that shorter loops are not associated with symptoms of sufficient severity to warrant operation. Thus the statement is made by Rankin, Bagen and Bue that hypertrophy and elongation of blind loops of ileum have been observed at necropsy years after resection of the colon with side-to-side anastomosis between the colon and small bowel (Fig 1). Similarly, Pickhardt reported a case of resection of the right portion of the colon and terminal part of the ileum with side-to-side anastomosis between the transverse colon and ileum in which

ileum. Nothing further was advised at that time since the sinus closed spontaneously. Two weeks later, however, fecal and purulent drainage again developed associated with marked constitutional symptoms and fever as high as 103 degrees F. Recovery from this attack was slow and after approximately 10 weeks surgical exploration of the anastomosis was carried out. The side-to-side anastomosis between the ileum and transverse colon was found to be functioning satisfactorily. There was a redundant blind segment of ileum distal to the anastomosis the lumen of which connected with the cotaneous opening. This loop of ileum had become hypertrophied and elongated. Ulceration had presumably occurred which had progressed to perforation. The operation was limited to excision of the redundant loop. The patient made an uneventful recovery and has remained well since.

CASE 2. A white man aged 48 years was seen in an emergency in July 1944. He had been awakened in the early morning by severe crampy abdominal pain which had gradually become worse. There was no accompanying vomiting but some nausea. One year previously repair of a left inguinal hernia had been carried out at the clinic. Ten days later mesenteric thrombosis had developed necessitating resection of approximately 28 centimeters of jejunum because of gangrene. Intestinal continuity had been re-established by means of side-to-side jejunojejunostomy.

On admission the patient's temperature was 100.4 degrees F., the pulse was 90 beats per minute and the blood pressure 120 millimeters of mercury systolic and 95 diastolic. The heart and lungs were normal. The abdomen was rigid and tender generally but tenderness in the right lower quadrant was most marked. Examination of the urine gave negative results. The leucocytes numbered 9,900 per cubic millimeter of blood. A scout film of the abdomen made without administration of barium revealed free gas in the peritoneal cavity.

Surgical exploration was carried out shortly after admission. The blind inverted end of the proximal segment of jejunum distal to the anastomosis was reddened, thickened and covered with fibrinous purulent exudate. The mesentery was thickened and edematous but there was no evidence of mesenteric thrombosis. When the region of the anastomosis was first approached about 30 cubic centimeters of thick pus was encountered. The blind end of the distal segment of the jejunum was 4 to 5 centimeters in length and showed no evidence of obstruction or inflammation. Both blind ends of bowel were excised and the ends reinverted so that no redundant segments were left. Pathologic examination of the proximal loop revealed inflammation with ulceration, abscess formation and perforation. The shorter distal loop revealed only mild inflammation.

Pneumonia developed postoperatively and in spite of treatment with penicillin and the sulfonamides the patient died 8 days after operation.

CASE 3. A white married woman aged 27 years first seen in August 1944 complained of intermittent

Fig. Side-to-side ileotransverse colostomy. a. Cor rect method, making united ends of bowel as short as possible. b. Slight dilation of proximal end of small bowel which normally occurs. c. Large dilated blind loop of small bowel which occurs when redundant loop is left too long.

attacks of crampy abdominal pain, vomiting, distention and constipation which had first developed after a partial resection of the small bowel 4 years before. The individual attacks often lasted as long as 4 days. In April 1940 the patient had undergone surgical exploration elsewhere and appendectomy, left salpingectomy, and suspension of the uterus had been carried out. In September 1940 65 centimeters of gangrenous ileum had been excised and a side-to-side anastomosis established between the segments of ileum.

Physical examination gave essentially negative results except for a ventral hernia which had developed in the scar of the former incision. There were no masses on pelvic examination. Leucocyte and erythrocyte counts were normal as was the urinalysis. Roentgenographic examination of the chest, stomach, gall bladder and colon was negative. Roentgenographic examination of the small bowel revealed a dilated blind loop of ileum near the former anastomosis which seemed adequate.

Surgical exploration of the abdomen was carried out in September 1944 and the previously established antiperistaltic side-to-side anastomosis between segments of the ileum was examined. The proximal blind end of ileum had become dilated and hypertrophied so that it exceeded the size of a normal stomach, being about 45 centimeters long and approximately 10 centimeter in diameter. Excision of the ileocecal stoma, including both blind ends of bowel, was carried out and intestinal continuity was

the blind loop of ileum became elongated and dilated without causing symptoms. He pointed out, however that the blind loop was a potential source of danger from the standpoint of obstruction.

We were able to find reports of a few cases, however in which serious symptoms were produced by redundant blind loops. Turner referred to a case in which a blind ileal segment, left after resection of the right portion of the colon with side-to-side anastomosis between the transverse colon and ileum ruptured when the patient fell downstairs. Eckel and Holman reported a case in which vague intermittent abdominal distress developed and persisted without change for 10 years after hemicolectomy on the right with side-to-side ileocolostomy. At subsequent operation a distended blind segment of ileum distal to the anastomosis was excised with complete cure of the patient. Sletten in a discussion of Pickhardt's paper mentioned a case in which such a blind loop perforated. Estes and Holm reported the case of a 16 year old boy in whom after resection of the terminal part of the ileum and establishment of a side-to-side anastomosis between the ascending colon and ileum, a short blind loop of ileum had been left distal to the anastomosis. A few months later intermittent pain, borborygmi and low abdominal distention developed. The blind segment had become hugely elongated, distended and ulcerated and filled almost a third of the abdomen. Resection of the blind loop resulted in complete relief of symptoms. Ginzburg, Colp and Sussman reported 3 cases in which blind loops of ileum gave rise to symptoms after side-to-side ileocolostomy with division of the bowel. In 2 of the cases the blind ends had been demonstrated clinically one by roentgen rays and the other by the palpation of a large sausage shaped mass. In the third case ulceration had developed in the blind loop and the patient had symptoms of obstruction. In all 3 cases cures followed excision of the blind redundant loops.

A search of the files of the Mayo Clinic revealed records of only 5 cases in which symptoms could be definitely attributed to blind segments of small bowel left after division of the bowel and side-to-side anastomosis be-

tween either the colon and small bowel or segments of small bowel. These 5 cases were selected from a larger number in which symptoms usually suggestive of partial intestinal obstruction and a redundant segment of bowel beyond the side-to-side anastomosis were noted. However in each of the excluded cases some other more probable explanation for the symptoms was found. In some cases a recurrence of the original disease, usually regional enteritis, had developed in others, the segments of the bowel which had been used in the anastomosis were bound down by adhesions or the anastomosis was greatly distorted. Finally some cases were excluded because of a malfunctioning stoma. It is possible that in some of the excluded cases the blind segment of bowel distal to the anastomosis was the underlying etiologic factor. However the findings, in such cases, at the time of the subsequent operation were so complex that the symptoms could not be attributed solely to the blind loops. Since we were primarily interested in the syndrome associated with the blind segments alone it was thought desirable to exclude all such complicated cases.

REPORT OF CASES

CASE 1. A white woman, aged 37 years, was first seen in August 1943. She complained chiefly of crampy pains and a mass in the right lower quadrant both of which had been present for 4 years. A diagnosis of regional enteritis was established. Resection of the terminal part of the ileum, hemicolectomy on the right and side-to-side ileocolostomy were carried out. A soft rubber drain brought out through a stab wound in the right flank, was left in the region of the anastomosis. The patient was discharged after an uneventful convalescence. She returned 6 weeks later because gas and feces were passing from the site of the previous drain. Gas had first passed from the stab wound about 1 month after the operation, and shortly afterward fecal material had begun to exud from the sinus. Crampy pain had been experienced intermittently in the right lower quadrant which was relieved by the expulsion of gas either through the rectum or through the draining sinus.

There was no systemic evidence of infection at the time of admission. The incision was well healed but the feces and gas exuded from the fistulous tract at the site of the previous drain. A small abscess had developed in the right groin. The leucocytes numbered 7,500 per cubic millimeter of blood. Roentgenographic examination of the colon revealed a freely functioning anastomosis between the colon and

become established prior to the operation or unless gross fecal soiling has occurred at the time of operation.

In all clinical cases which have been reported including those in the present series, some time elapsed between the operation and the development of the complication. When localized infectious processes occurred ulceration evidently developed first with subsequent perforation of the ulcer. The ulceration alone seemed to produce no definite symptoms and the first evidence that any complication had developed was produced by the inflammatory process outside of the bowel. Thus in Case 2 of our series all symptoms were obviously produced by the local peritonitis, in Case 1 the earliest symptoms were those associated with an external fecal fistula and in one of Gunzburg, Colp and Sussman's cases, an inflammatory mass secondary to ulceration produced obstruction. We have no evidence in our material that the inverted end of the proximal segment ever gave way and the only case of rupture of a redundant loop that we were able to find in the literature was that reported by Turner which clearly resulted from trauma.

In all the other cases in the present series as well as in those we were able to find reported in the literature a fairly uniform syndrome was noted. The symptoms developed at varying times after operation and were generally speaking suggestive of partial intestinal obstruction. When the redundant loop was sufficiently hypertrophied distention was evident clinically; this occurred in Case 1 of the present series and in a case reported by Estes and Holm. More frequently than not there was no evident distention. All patients with chronic symptoms complained of colic of varying intensity. Diarrhea was associated with the colic in Case 4 of our series and vomiting accompanied the colic and distention in Case 3.

In cases in which perforation and symptoms consequent to peritonitis do not occur the diagnosis depends on the demonstration of the redundant loop by roentgenography after administration of barium. In cases in which the redundant loop is of clinical significance it should be demonstrable on roentgenologic

Fig. 2. Redundant, dilated blind loop of small bowel following side-to-side ileocolostomy (Case 5).

examination after barium has been given either as an enema or by mouth (Fig. 2). It is conceivable that the redundant loop could be packed so solidly with inspissated stool or secretion that barium could not enter. However this is probably an unusual circumstance and in such cases the redundant loop should be palpable on clinical examination. A note of caution could well be sounded concerning the use of barium by mouth in patients who have undergone previous resections of the bowel and who have since had symptoms suggestive of partial obstruction. The symptoms in such cases are far more likely to be due to partial obstruction produced by adhesions or an inadequate stomach than to redundant loops and in such cases barium by mouth may be strongly contraindicated.

Some restraint should be exercised as well in attributing the symptoms to a redundant segment which may be demonstrated by roentgenography. We have noted repeatedly at the second stage of a staged resection of the right colon that redundancy had developed

re-established by an end-to-end anastomosis between segments of ileum. Patient has remained well since.

CASE 4. A white woman, aged 66 years was first seen in November 1944. For 3 years she had had diarrhea and crampy abdominal pain chiefly localized in the right lower quadrant of the abdomen. For the preceding 7 years in addition she had experienced in the right upper quadrant, attacks of pain of a different type which were characteristic of those associated with cholelithiasis. Abdominal exploration had first been carried out elsewhere in 1933 because of the recurring attacks of pain in the upper right quadrant. At that operation the right portion of the colon and terminal part of the ileum had been resected and intestinal continuity had been re-established by means of side-to-side ileocolostomy. Shortly after that operation the intermittent attacks of crampy abdominal pain, localized in the right lower quadrant along with diarrhea had first developed.

On physical examination the blood pressure was found to be 115 millimeters of mercury systolic and 120 diastolic. The heart and lungs were normal. The abdomen was moderately tender in the right lower quadrant. Urinalysis erythrocyte count, and a hemoglobin determination gave normal values. The leucocytes numbered 15,500 per cubic millimeter of blood. Roentgenographic examination of the chest and stomach gave negative results and examination of the colon revealed a normally functioning stoma between the ileum and transverse colon. A cholecystogram disclosed a nonfunctioning gall bladder and cholelithiasis.

At operation the ileocolic stoma which had been made previously was examined and found to be adequate. The inverted end of ileum was hypertrophied and extended for a distance of approximately 15 centimeters beyond the anastomosis. The redundant loop of ileum was excised and the end turned in. The gall bladder was also removed.

The patient returned to the clinic for a check-up in November 1945. No pain had been experienced since her dismissal. In August, 1946 in response to an inquiry the patient indicated that she was experiencing some distress in the right lower quadrant.

CASE 5. A white man aged 31 years, first came to the clinic September 9, 1935 complaining of intermittent crampy abdominal pain since May 1915. In 1939 a diagnosis of regional enteritis had been made elsewhere and in 1941 an abdominal exploration had been carried out. Nothing was done surgically to treat the regional enteritis at that operation. His symptoms became progressively more severe and in 1943 a stage hemicolectomy on the right and side-to-side ileocolostomy had been carried out elsewhere. Symptoms recurred and became so marked that a second resection of the terminal portion of the ileum including the site of previous ileocolostomy, had been performed in April 1945. Continuity of the bowel was again re-established by means of side-to-side ileocolostomy. The intermittent crampy pains which caused the patient to come to the clinic had developed about a month later.

Physical examination on admission gave essentially negative results with the exception of slight tenderness in the right lower quadrant of the abdomen. The value for hemoglobin was found to be 10.4 grams per 100 cubic centimeters of blood. The leucocyte count was 4,200 per cubic millimeter of blood and urinalysis gave negative results. Roentgenographic examination of the colon revealed a normally functioning stoma between the ileum and transverse colon and a dilated blind loop of ileum proximal to the anastomosis. In view of the number of operations the patient had undergone and the mildness of the present symptoms, conservative management was advised. The patient returned approximately 6 months later, partly because a further check-up had been advised but chiefly because the attacks of crampy pain had occurred with increasing frequency and had become increasingly severe during the interval. Borborygmi and distention accompanied the attacks at that time. Relief occurred when the gas seemed to pass some obstruction. Roentgenographic examination of the colon again revealed a normally functioning stoma between the ileum and transverse colon and the presence of the dilated blind loop of ileum. A delayed film showed prolonged retention of barium in the blind segment of ileum (Fig. 2).

Exploration was advised and carried out in April 1946. The redundant segment of ileum was hypertrophied and dilated. The blind loops of ileum and colon along with the site of anastomosis were resected and an end-to-end anastomosis was established between the ileum and transverse colon. The patient made an uneventful recovery and has since regained his normal weight and has remained well.

COMMENT

In view of the reports of cases in the literature and those in the present series, there can be no doubt that potential hazards, associated with the closed end of the proximal segment of bowel are inherent in the operation of side-to-side anastomosis after division or resection of the bowel. To produce symptoms in dogs, long segments of bowel must be left beyond the anastomosis, and this fact probably explains why clinical cases are uncommon, in that such gross errors of technique are seldom made. Whether the closed end of the proximal segment has any particular tendency to leak early postoperatively and so produce peritonitis cannot be stated. The findings at necropsy in such cases are often inconclusive because of the extent of the local inflammatory reaction. However early death from peritonitis following resection and side-to-side anastomosis is unusual unless peritonitis has

distal to the anastomosis in the end of the proximal segment of bowel after division of the bowel and side to-side ileocolostomy (Fig 1b). Such a finding formerly gave us concern and we have occasionally excised such small redundant segments at the same time that the second stage of the operation was done. However these short redundant segments had produced no symptoms they have been observed at necropsy in patients who had lived for prolonged periods without symptoms after operation and in studies in animals short loops do not become the sites of complications. We now believe that some redundancy may develop in the end of the proximal segment virtually irrespective of how little bowel has been left beyond the anastomosis and that such redundancy causes no symptoms and gives rise to no complications. It is evident that the mere presence of some redundancy is not an indication for its removal.

The method used to re-establish continuity of the bowel after resection of the terminal portion of the ileum and the right part of the colon varies with the surgeon end-to-side end-to-end and side-to-side anastomosis are all commonly used and each has its advocates. Results following the three methods are comparable and the risk associated with each seems much the same at least in the hands of surgeons thoroughly familiar with the particular method used. Since other satisfactory methods are available it follows that side-to-side anastomosis should probably not be used if the method is to be associated with serious potential hazards. The scarcity of reported cases of serious complications, the rarity of serious complications among our cases and the gross error of technique which must be made to produce the complications in dogs would all argue strongly that complications associated with the blind end of the proximal loop following side to-side anastomosis are not of great importance and cannot be used to condemn the method. While we are not committed to the exclusive use of any one of the three methods to restore continuity of the bowel after resection we tend to employ side to-side anastomosis particularly after right hemicolectomy (Fig 1a). With this type of anastomosis the mesenteric attachment to the

bowel wall presents no problems and the stoma can always be made of ample size. In short this method of anastomosis seems easier technically to us than either the end-to-side or the end-to-end methods. It was chiefly because of this preference that the effort was made to evaluate the hazards associated with the inverted end of the proximal segment of bowel. It is evident that complications associated with the inverted proximal end are successfully avoided in the great majority of cases.

CONCLUSIONS

- 1 The potential hazards associated with the inverted end of the proximal segment of bowel following division of the bowel and side to-side anastomosis are dilatation and hypertrophy ulceration and perforation.
- 2 Some dilatation and hypertrophy of the proximal end of the bowel distal to the anastomosis develop in many cases but symptoms are rarely produced.
- 3 When longer than usual lengths of the proximal segment are left distal to the anastomosis symptoms suggestive of partial obstruction may develop. The colicky pains occur in attacks and may be accompanied by vomiting and diarrhea.
- 4 Complications associated with the inverted end of the proximal loop are unusual as judged by the rarity of the reported cases and by the rarity of cases in our own series. They are largely preventable by avoiding redundant segments of the proximal end of the bowel distal to the anastomosis.
- 5 Such complications are so unusual that they do not detract from the usefulness of side-to-side anastomosis.

CALCIFICATION OF THE SUPRASPINATUS TENDON INFILTRATION THERAPY WITH LOCAL ANESTHESIA AND MULTIPLE NEEDLING

I NORWICH M.B. F.R.C.S. (Edin.) Johannesburg South Africa

THE object of this paper is to discuss in detail the infiltration therapy of calcification of the supraspinatus tendon with local anesthesia. The supraspinatus tendon which is really only one component of the musculotendinous cuff and which is inserted into the greater tuberosity of the humerus is the victim of degeneration, calcification and rupture. These three conditions are quite separate clinical entities but probably result from the same basic anatomical peculiarity of this tendon. The etiology, incidence, pathogenesis and treatment are described.

GROSS ANATOMY

The supraspinatus tendon which is one component of a fused structure aptly called by Codman the musculotendinous cuff is inserted into the greater tuberosity of the humerus. In this region of the shoulder there are many important and interesting anatomical features. The subacromial or subdeltoid bursa which is really a synovial bursa lies beneath the deltoid muscle, the coracoacromial ligament and the acromion process itself intervening between these structures and the supraspinatus tendon. The supraspinatus tendon forms part of the floor of this bursa. This bursa is roughly circular and appears to increase in size with age. Its main function is to permit the upper end of the humerus with its capsule to glide easily under the coracoacromial ligament and the acromion process during the movement of abduction. The subacromial bursa is considered to be indispensable in abduction and rotation of the humerus, but it has been removed on more than one occasion without interfering with the function of the arm. The three short rotators, supraspinatus, infraspinatus and teres minor tendons flatten out as they approach their insertion and blend almost indistinguishably with the floor of the subacromial bursa and

capsule of the shoulder joint. The edges of these tendons are so closely approximated here that it is often difficult to tell where one stops and the next begins. It is this fused structure that is referred to as the musculotendinous cuff. The average length of the supraspinatus tendon is $2\frac{1}{4}$ centimeters.

The attachment of the tendons of these short rotator muscles takes place through most of the upper half of the sulcus which is called the anatomic neck of the humerus. The heavier portions of the tendons are inserted on facets situated on the great tuberosity.

The majority of the pathological lesions around this vulnerable area of the shoulder region result from either acute or chronic trauma and involve not only the musculotendinous cuff but also the subacromial or subdeltoid bursa. The one may be secondary to the other so that when considering pathology here all possible lesions must be visualized.

The supraspinatus tendon is subject to degeneration, rupture and calcification and the subacromial bursa above it to acute or chronic bursitis. The pathology of an acute rupture of the supraspinatus tendon was first recognized by Smith in 1835 and fully described as a clinical entity by Codman in 1911. Acute rupture, partial or complete, due to a sudden abduction violence must be distinguished from a rupture of a few fibers of the tendon already degenerated by the gradual attrition of the movement of abduction against the prominent acromion process and its associated coracoacromial ligamentous arch. The actual causation of such degeneration is not fully understood. Senile degeneration of the tendon is postulated as one theory but it occurs in very young adults. It is also suggested that deterioration of blood supply to the tendon may play some important part. Most surgeons however are of the opinion that degeneration

is due to the wear caused by long continued use of the arm in abduction and associated with friction against the coracoacromial arch. Heredity has not yet prepared the human shoulder against the tension and friction of the supraspinatus tendon of the typist, machine worker or hairdresser. Whether occupation alone causes an ischemia due to compression of vascular supply or attention because of friction is still problematic.

CALCIFICATION OF THE SUPRASPINATUS TENDON

Painter in 1905 was the first to recognize calcium deposits in x-ray films of the shoulder. He believed the shadows he observed were due to a thickening of the subdeltoid bursa. Codman, however, who was present at one of Painter's operations, was the first to realize that the deposit was actually in the supraspinatus tendon. It has been observed that gross pathological anatomy reveals a deposition of calcium in the short tendons of the shoulder capsule, most frequently situated in the supraspinatus tendon. On the base of the subacromial bursa in the tendon involved there is an elevation with a grayish white center and a red turgid periphery (2) resembling a boll (5). It is important to note that the bursa itself contains a fibrinous exudate. The calcium deposit at this stage is soft and creamy and resembles staphylococcal pus, or it may be firmer and of the consistency of tooth paste. The acute symptoms are probably caused by involvement of the base of the subacromial bursa. The calcium deposit may rupture into this bursa, producing a chemical bursitis (according to Bishop) and the site of rupture may often be demonstrated at operation (Brickner).

Microscopically the calcium deposits may occur as a number of foci of varying size embedded in a tendon which shows fibrosis and is infiltrated with masses of chronic inflammatory cells, mostly lymphocytes and plasma cells with a few giant cells. The connective tissue may show hyalinization according to a description by Moschowitz.

Chemically the composition of the calcium has been reported by many authors (6, 14, 17) as occurring in the form of calcium carbonate and calcium phosphate and some analyses

show calcium oxalate. The analyses have differed greatly as to the proportion in which these calcium salts occur.

INCIDENCE

The only reliable figures of the incidence of calcification of the supraspinatus are those of Bosworth—among 6,661 supposedly normal persons of the "white collar" class, calcification was found on routine fluoroscopic examination in 165—2.7 per cent in one or both shoulders. In this series the lesions were found most frequently in the period of greatest activity of adult life, nearly all of his subjects being under 50 years of age. It occurs more often in males—3.6 per cent in 1,178—while among 3,883 females it was only 2.5 per cent.

Not every calcification is therefore a subject of symptoms. The soil, however, is fertile for rupture of tendinous fibers with subsequent acute or chronic symptoms.

ETIOLOGY AND PATHOGENESIS

Occupation. Typists, hairdressers and machineists appear to have a significantly higher incidence of calcium deposits. Long continued use of the arm in abduction seems to be a predisposing feature.

Infection. The assumption that infection plays any part—locally or through septic focus—has never been proved. Many who have operated on these deposits and made bacteriological cultures have found negative results.

The sequence of events leading up to the actual deposition of calcium appear to be primarily an interference of blood supply to the tendon. There is, however, controversy how this is brought about. Codman and Wright advanced the hypothesis that calcium is laid down in the unabsorbed hemorrhage which fills the defect in an abortive attempt at repair of minor traumas to the tendon tissue which normally has a poor blood supply. Moschowitz and Elmslie arrived at a similar conclusion. Carnett recorded his opinion that the deposits are as a rule quiescent in their formation and are due to tendinitis, local necrosis of tendon and calcification produced by repeated occupational traumas which squeeze the supraspinatus tendon between the tuberosity of the humerus and the roof of the sub-

Fig. Case 2. Mrs. J. Y. a. Calcified supraspinatus day before treatment; b, day after infiltration and movement; c, 8 days after N.T. absorption of periphery; d, 3 days after infiltration treatment, calcification becoming

more "woolly" and elongating; e, 23 days after calcification, overflowing its banks; f, 36 days after initial treatment, almost complete absorption after having "overflowed" its banks.

the deposit has formed mild trauma will produce in some the acute inflammation with characteristic symptoms or in others chronic signs and symptoms. Acute symptoms may even be superimposed on the chronic condition. Calcium deposits have been observed to disappear with and without treatment. The acute inflammation with its increased blood supply and accumulation of inflammatory cells steps up the local metabolite rate with subsequent production of carbon dioxide in sufficient amount to lead gradually to dissolution of the calcareous deposits. An acutely inflamed deposit may rupture into the subacromial bursa, setting up a bursitis. This may

also perhaps explain the acute attacks in which there is rapid recovery without treatment.

Acute phase An acute attack may appear without warning even during sleep or it may follow some abduction type of trauma such as preventing an object from falling with the arm in extreme abduction, a fall on the outstretched hand or sudden forcible abduction. It may also develop during the course of a subacute or chronic attack. The patient immediately develops excruciating pain, abrupt and violent, with complete limitation of all movements at the shoulder joint. The pain is felt over the bursa and over the insertion of the deltoid muscle. The pain produces reflex spasm of the

whole shoulder girdle causing pain down the arm and forearm even into the fingers which is so often diagnosed as 'acute brachial neuritis'. It is possible that such a neuritis is really the acute phase of supraspinatus calcification. This reflex spasm is known to produce the typical clinical picture of the scalenus anterior syndrome on the affected side.

Atrophy of the spinatus muscles occurs if the symptoms last more than a few weeks. A lump may be felt just medial to the greater tuberosity if the deposit is in the supraspinatus tendon. If untreated such an acute phase may last for several weeks and then revert to a chronic type with the possibility of adhesion formation or it may clear up fairly rapidly especially if the deposit ruptures into the sub-acromial bursa.

Chronic phase The onset is insidious. First there is an uncomfortable feeling around the shoulder later it is hard to find a comfortable position in which to rest the arm at night during elevation of the arm in the coronal plane. Pain is most often felt at the fibers of insertion of the deltoid muscle while the maximum point of tenderness is over the deposit in the tendon close to the greater tuberosity. If there has been a long painful period the whole area becomes sensitive with pains shooting up into the neck and down to the hand. This has given rise to the misnomer 'chronic brachial neuritis'. In some cases the hand has been seen to swell and the skin to become atrophic. There is usually a certain amount of spasm and limitation of abduction and external rotation at this point. Definite painful 'hitches' associated with abduction through 70 to 100 degrees are commonly present and referred to as Dawbarn's sign when the painful hitch reappears through the same arc on the descent of the arm. Acute exacerbations may occur at any time during the chronic course.

X ray examinations For all suspect cases of calcification of the supraspinatus x ray investigations should be employed and spot roentgenograms taken as suggested by Bishop. The deposit must be seen in profile or it will be obscured by the underlying bone. Deposits of calcification may be single or multiple and if liquid may be seen to change its shape with movement. Sometimes at operation a milky

Fig. 3. Case 3. Mr J. J. H. a, Before infiltration and movements; b, 3 days after almost complete absorption. Note here also dissemination of calcified deposit beyond its original confines.

fluid containing calcium has been found which did not show up on x ray examination.

Diagnosis The diagnosis of the acute phase is usually confirmed and fairly easily established by a history of something wrong previously in the shoulder aggravated by some slight trauma. The acute symptoms are often excruciating with almost complete limitation of movement of the shoulder. A localized area of maximum tenderness below the tip of the acromion process—a painful 'hitch' on abduction and again on descent—and the disappearance of the tenderness of the fully abducted arm beneath the tip of the acromion are of sufficient importance to diagnose pathology in the supraspinatus tendon in the lesser acute lesion. The x ray appearances are pathognomonic especially if these are of the semi soft technique. Calcification in a milky form containing calcium has been known to be present without showing up on test x ray films (2).

TREATMENT

Chronic phase The efficiency of treatment of the chronic forms is difficult to evaluate because the patient will get better in spite of any real form of active therapy although it may take up to 2 years for the deposit to become absorbed. Removal of the calcium by operation gives the most satisfactory result although recovery is slower than in the case of an acute deposit. Patients however always prefer some form of heat therapy and over a period of time they recover. The increased

Fig. 4. Case 4. M. J. A. G. a, b Before infiltration therapy c, 11 days after complete absorption

vasculantly with heat therapy and deep x ray therapy and the resulting high carbon dioxide content of the tissue makes the medium acid so that calcium is absorbed. The use of immobilization in abduction causes adhesions and is mentioned only to be completely condemned. Active repeated movement must be the golden rule from the very onset of therapy.

Acute phase. Many forms of treatment have been advocated for the acute attack. Most authors Hitzrot, Bosworth, Codman, Moseley appear to favor excision of the deposit through the same incision as exposure for a ruptured supraspinatus tendon. Irrigation by the two needle method of Patterson and Darvach has been advocated for acute attacks. It is an operative procedure and while good results have been reported by those who favor the method it is not very satisfactory for solid calcium. Short wave diathermy and deep x ray therapy are advocated to produce hyperemia to aid rapid absorption of the calcified deposit.

It is proposed in this paper to describe in detail the treatment employed by the author for the past 5 years for the acute form of supraspinatus calcification. It was felt that in accepting Wells's hypothesis for pathological calcification a more simple method of rendering the medium acid could be achieved than a surgical operation. The method employed is local anesthetic infiltration of the calcifica-

tion and multiple needling of the deposit or whatever capsule may envelope it. This is followed by immediate and continuous movement of the affected shoulder.

Technique of infiltration therapy. The acute cases only are handled with this method as experience has shown that the more acute the pain and the more limited the movement the better are the results.

The patient is either seated or lying, and after thorough cleansing of the skin the area around the acromion process is infiltrated with 1 per cent novocain or procaine solution. The deeper structures are gradually anesthetized and the needle is passed almost horizontally and slightly backward keeping it just parallel to the under surface of the acromion process all the time. These deeper structures must be well infiltrated otherwise the patient experiences excruciating pain. When the deposit is reached it is easily recognized by a grating sensation. The needle is then changed to a fairly wide bore. The deposit is then thoroughly infiltrated with another 10 to 15 cubic centimeters of 1 per cent novocain changing the direction of the needle all the time as the fluid is injected. After the infiltration, the needle is repeatedly withdrawn from the deposit and reintroduced about 7 to 10 times (the needle is not withdrawn from the skin in performing these multiple pricks). The usual care is

Fig. 5. Case 5. Mr C. K. a, left, Extensive calcified mass before infiltration therapy b, 28 days after almost complete absorption

taken to determine any sensitivity to the local anesthetizing fluid employed. It is essential to carry out these injections carefully and gradually and to see that the needle is in the deposit each time it is withdrawn and reintroduced. In about 10 to 30 minutes varying with each case the acute agonizing pain disappears and the completely immobilized shoulder can now be moved fairly freely in all directions. The patient is instructed in all movements of the shoulder especially full 180 degree abduction internal and external rotation. A fully experienced trained physiotherapist is employed to instruct the patient in all these movements. The patients are very happy about the miraculous relief of pain effected by this local anesthetic injection but they must be informed that such relief is to be short lived and that the pain will recur and perhaps be even worse in a few hours.

The stiffness however does not reappear to the same extent and the patients are impressed with the necessity of continuing the movements of the shoulder no matter how limited or painful. These injections are preferably carried out in the morning so that movements can be continued in the afternoon. Sedatives are prescribed for the recurrence of the pain.

The patient is seen thereafter daily to ascertain and instruct movement of the shoulder and if necessary daily x ray films are carried out to note the progress of absorption of the calcified deposit. The pain although worse soon after the injection is better the next day and gradually improves and in the majority of our cases the acute pain disappeared in an av-

Fig. 6. Case 6. Mrs F. C. a, left, Before infiltration b, 23 days after almost complete absorption

erage of 10 days. The relief from pain is proportionate to the rate of absorption of the calcification. If the movements are diligently and intelligently carried out then the rate of absorption of the calcification is complete in an average of 3 to 4 weeks. Radiant heat to the shoulder was utilized in those patients who experienced more pain than anticipated.

RATIONALE OF INFILTRATION THERAPY

The rationale of this infiltration therapy depends on the production of hyperemia in the region of the shoulder. This is achieved by allowing the shoulder to move in all directions as soon as possible and which is made possible only by the use of a local anesthetic. The local anesthetic therefore is not the active principle of this therapy but merely an aid to the production of hyperemia. Secondly the repeated

TABLE I—SUMMARY OF 7 CASES

Case description	Previous history X ray appearance	Treatment	Relief and rate of absorption of deposit	Follow-up
M. L. W. Houseman	Chronic pain for months. No trauma. Sudden acute agonizing pain. Ex- tremity calcified deposit of supraspinatus	infiltration 10 cc. procaine 1% with 1 cc. normal saline. Multiple needling.	Immediate relief. Pain returned in 1 hour, but movements remained improved. Deposit absorbed in 5 days. See Figs. 1a, b.	Pain in 30 days. No movement. No pain.
Mrs. J. V. Housewife	Gradual pain for 6 days. Then sudden acute onset. No trauma. Extremity calcification of supraspinatus.	infiltration 10 cc. procaine 1% with 1 cc. normal saline. Multiple needling.	Immediate relief. Pain returned worse than before. Deposit remained in surrounding area—overlaid on scapula. Almost complete absorption in 30 days. See Figs. 2a, b.	10 weeks later. No movement of joint. No pain.
M. J. H. Book repairer	No previous history but wrenching accident on train (streetcar) in abducted position. Progressive calcification of supraspinatus.	infiltration 10 cc. procaine 1% with 1 cc. normal saline. Multiple needling.	Immediate relief for about 1 hour. More movement. Almost complete absorption in 4 days. Pain returned in 10 days. See Figs. 3a and 3b.	Lived out years. No pain. No movement. No pain.
M. J. A. Active farmer	No previous history. No trauma. Sudden acute agonizing pain and wrist clasp. Rounded and fragmented calcification.	infiltration 10 cc. procaine 1% with 1 cc. normal saline. Multiple needling.	Immediate relief lasting 1 hour. Good movements thereafter. Complete absorption in 30 days. See Figs. 4a and 4b.	X rays 10 months later. No movement. No pain.
M. C. K. Housewife	Previous gradual ache. Then sudden severe pain as if stiff about for 10 days. Very extensive and fragmented calcification.	infiltration 10 cc. procaine 1% with 1 cc. normal saline. Multiple needling.	Immediate relief for 6 hours. Recurred as bad, but movements better. Almost complete absorption in 30 days. See Figs. 5a and 5b.	Pain for 10 days. No movement. No pain.
Mrs. F. L. Housekeeper	First noticed pain in shoulder 10 months previously. Diagnosed as rheumatism. Swelling without trauma. Acute phase. Fragmented, lower calcification.	infiltration 10 cc. procaine 1% with 1 cc. normal saline. Multiple needling.	Immediate relief lasting for 3 hours. Complete absorption in 30 days after. See Figs. 6a and 6b.	10 months later. No movement. No pain.
M. H. M. Accountant	No previous history. Sudden wrenching at work. Acute agonizing pain with limited movements. Very faint fragmented calcification.	infiltration 10 cc. procaine 1% with 1 cc. normal saline. Multiple needling.	Immediate relief and movements lasting 3 hours. Recurred worse than before but movements better. Complete absorption in 30 days. See Figs. 7a and 7b.	Pain for 10 days. No movement. No pain.

multiple puncturing of the deposit allows the soft calcification to overflow its banks (Case 2 Fig. 2c) thereby disseminating the calcification into surrounding planes which in turn absorb it at a quicker rate. It has been observed by Wilson that an inflamed calcified deposit may rupture into the subacromial bursa, setting up a bursitis. This may perhaps explain the acute attacks with rapid recovery without treatment as described by Codman.

The mechanical irritation produced by the needle usually results in infiltration of inflammatory cells which increases local metabolism which in turn helps absorb the calcification.

The sum total of all these factors hastens the absorption of the calcified deposit and in actual practice this form of therapy has been highly successful in 15 cases. Many of the failures of this method are probably due first

to inadequate infiltration and needling of the deposit and second to lack of immediate and daily movement of the shoulder joint. The recurrence of the pain which as already stated is very often worse than the original discomfort has led orthopedic surgeons and others to condemn this form of treatment but perseverance and the use of sedatives can overcome this discomfort. Many are apt to expect too much at once with a single needling of the deposit. If this technique is carried out many excisions of calcified supraspinatus deposits can be avoided which is after all an operation like any other. This infiltration and needling therapy is simple quick and can be carried out with the patient ambulatory. Not more than one injection has been necessary in the real acute case although two and three have been used for the subacute phase.

This infiltration therapy has been used in a few cases of acute painful shoulder with localized subacromial tenderness and especially in those associated with a painful 'hitch,' but without a calcareous deposit. In these the results have been most favorable and the relief as dramatic and prompt as the tendinitis with calcification. It is possible that in these shoulders the musculotendinous cuff is in the pre-calcification phase. This therapy has not been used for the calcification found accidentally.

The amount of local anesthetic fluid injected appears to have no direct influence upon the results obtained except that the solutions should be injected directly into the deposit. If there is any doubt as to the exact location of the needle x rays of the needle *in situ* are taken to determine the exact position.

No originality is claimed for this form of infiltration therapy. As far back as 1913 Flint of Yale reported prompt relief of symptoms by aspiration under local anesthesia. A year later Sievers (1914) in Germany, cognizant of Flint's publication described the case of another patient similarly treated with success. Halde, Haggart and Allen and Ferguson have all described the use of local anesthesia for painful shoulders but many appear to have confused acute subacromial bursitis and true calcification. Lapidus in an excellent article on acute tendinitis with calcification describes this infiltration therapy with marked success in 16 cases of the acute phase of calcified tendinitis of the shoulder. He also includes collectively similar conditions around the elbow, hip, knee and wrist joints and refers to them there as acute tendinitis with calcification which are treated with similar favorable results by this infiltration therapy.

Results. Fifteen patients have been treated with this method with a follow up of periods varying from 7 months to 4 years. Table I summarizes 7 of these cases. The accompanying x ray films show the rapid complete absorption with this local anesthesia infiltration multiple needling and movement therapy

SUMMARY

The gross anatomy of the musculotendinous cuff of which the supraspinatus tendon is a component is described. The pathogenesis

and etiological factors of calcification are subject to wide difference of opinion but occupation appears to play an important rôle. The actual deposit of calcium is believed to be due to a low carbon dioxide content and a consequent high alkalinity resulting from a diminished blood supply. The incidence of calcification in individuals with no symptoms is 2.7 per cent in the largest reliable series of 12,122 persons detected on routine x ray examinations.

The close relationship of trauma to the deposition of calcium salts in the supraspinatus tendon may be explained by the rupture of some of the degenerated fibers producing an acute or chronic tendinitis. This phase probably causes the acute or chronic symptoms.

The acute and chronic phases are described and also the various treatments recommended.

A simple nonoperative therapy of local anesthesia infiltration and multiple injections of the deposit is described together with a detailed description of 7 cases. An essential feature of this therapy is immediate and continued movement of the shoulder joint.

Reproduction of x ray films are presented illustrating the rapid absorption of the calcified deposits in the acute lesions only and one series especially depicting the calcareous deposit overflowing its banks into the surrounding tissues.

THE INDICATION FOR POSTERIOR TRANSPIEURAL BRONCHOTOMY IN THE MANAGEMENT OF INTRABRONCHIAL TUMORS

HIRSH T. LANCSTON, M.D., F.A.C.S., Chicago, Illinois, and ROBERT T. FOX, M.D.
Hines, Illinois

By posterior transpleural bronchotomy is meant an opening made in the posterior or membranous portion of the bronchus after this structure has been exposed by transpleural thoracotomy.

Conclusions based on experience with a single case are obviously to be regarded as provisional because such experience is inadequate to justify approval or condemnation of any surgical procedure. However because of the rarity of the clinical picture which lead us to use this approach and the very gratifying end result obtained in this case we feel compelled to add such experience to the literature.

Floeser in 1940 reported the use of this procedure and Goldman referred to the exhibition of bronchotomy in the management of bronchial tumors in May, 1946 but the recent literature fails to indicate any use of this approach otherwise.

Assuming that the recent advances in the control of infection as well as thoracic surgery in general now permit this approach to be practical its position in such evolution would properly fall one step ahead of segmental resection in aiming at eradication of disease with minimal sacrifice of useful lung. Thus after thoracic surgery had passed from its incipient phases and intrathoracic procedures became relatively standardized resection in the form of lobectomy or pneumonectomy was the preferred treatment for many types of pathologic states. As the details of anatomy of the segmental hila became well understood conservation of undamaged lung tissue by resection of the involved segments

only emerged as the ideal. Now as a further step along these lines judgment is required of this ultimate attitude in the conservative lung.

Bronchotomy is not a new term nor is it a recently conceived operative procedure, it must be considered as a revival of an old concept which perhaps only now is of practical application due to the present day adjuncts to surgery namely anesthesia and antibiotic therapy.

Bronchial obstruction has interested physicians for a long time. Without entering into a complete review of the literature the developmental history of the management of this condition can be outlined.

Inhaled foreign bodies were the chief concern of the older physicians. The interest in other forms of bronchial obstruction such as tumors, had to await the introduction of bronchoscopy by Millan (1897) and its expansion by C. Jackson (1904).

DeForest Willard in 1891 conducted animal experiments to explore the feasibility of removing intrabronchial foreign bodies by a transthoracic bronchotomy. Prior to this time inhaled foreign bodies were treated by tracheotomy, often called bronchotomy, followed by blind grappling within the air passages for the offending agent. Such procedures were not very successful and the principle dependence was on spontaneous expulsion, the tracheotomy wound serving as an easier avenue of escape than the rima glottis. In those days the difficulties that were presented to a surgeon dissecting into the hilum of the lung were considered quite unmountable. Nevertheless bronchotomy either by a transpleural or transmediastinal approach was attempted in the succeeding years. Most of them ended fatally either eventually or immediately (1-7).

Fig 1 Roentgenogram of November 20, 1946 showing the atelectasis of the lower lobe

Fig 2 Roentgenogram of December 10, 1946 showing evidence of progressive obstruction now involving the upper lobe as well as the lower. The lipiodol is residual from an earlier bronchogram

but a successful one was performed for example, by Goeltz in August, 1904.

With the perfection of bronchoscopy attention seems to have become focused on this accurate and logical means of attacking problems of intrabronchial pathology. As the sequelae of bronchial obstruction become understood and emphasized resection of the involved lobe or segment thereof become the treatment of choice not only for foreign bodies inaccessible to endoscopic management but also for tumors not manageable by this approach (8).

If speculation is permissible the idealized indication for bronchotomy in the relief of neoplastic bronchial obstruction would involve a benign pedunculated tumor not manageable endoscopically obstructing a stem bronchus without irreversible lung damage distal to it. A stem bronchus is chosen because in the present state of our experience such a tumor involving a lobar bronchus only would be handled by lobectomy with a very high degree of safety.

The hazards anticipated in performing bronchotomy must include at least (1) the grave danger of pleural and mediastinal contamination by the secretions retained distal

to the obstruction (2) the reticence with which the affected lung or lobe will re-expand following relief of the obstruction enhancing therefore the danger of empyema (3) the leaving of the patient with a severely diseased lobe or lung most probably in the form of bronchiectasis (4) the possibility of tension pneumothorax or mediastinal emphysema

Fig 3 Photograph of excised endobronchial tumor against a centimeter scale. The very narrow pedicle is clearly shown.

Fig. 4. Early postoperative roentgenogram showing evidence of re-aeration of the left lung. The left pleural cavity contains loculated fluid, not being adequately evacuated by the drains. Although it was feared that organization might occur, satisfactory re-aeration took place.

from a leak at the site of bronchial incision and (5) the possibility of a bronchial stenosis developing at the site of bronchial suture.

CASE REPORT

J. I. F., male, white, age 26 years. The history of chest disease began in March 1946 while patient was working as a welder at which time he noted the rather sudden onset of a cough accompanied by shortness of breath. He consulted a physician who advised hospitalization. Instead of accepting this advice he returned to work after a week. The cough and shortness of breath had abated somewhat but were still present and seemed to become progressively more noticeable. In November of 1946 he was finally worse and his pneumonia was severe. A roentgenogram taken at that time revealed atelectasis of the left lower lobe (Fig. 1). Bronchoscopy was reported as revealing an intrabronchial mass completely obstructing the left lower lobe.

By the time of admission to our care his condition had deteriorated noticeably. Dyspnea was so severe that oxygen was required even when he was recumbent. Fever to 104 degrees of a septic type was present. The roentgenogram (Fig. 2) indicated now that the upper lobe was also obstructed. The septic lung no doubt due to the extensive retention of sputum in this completely atelectatic left lung.

As soon after admission as seemed permissible a bronchoscopic examination was carried out (Decem-

ber 31, 1946). This examination revealed an appearing trachea and right bronchus by 5 to 6 centimeters from the carina on the left, where the lumen was completely obstructed by a firm mass which was smooth, not ulcerated, not glistening in appearance and pink in color. It was firm in consistency but resilient in character. It could not be displaced downward in the bronchial tree even though at no point of its excursion this mass disappeared from view in the bronchus. It could have any attachment to the bronchial wall concerned. The long aspirating cannula could be passed past this mass without significant difficulty and could be aspirated from beyond it. The mass was distinctly cratered that this mass had crept up the bronchial lumen but was probably pediculated. By no means could the pedicle be seized and the obvious longitudinal extent of the mass precluded prompt removal by endoscopic resection. A biopsy was taken.

This procedure brought about some improvement in his clinical condition even though no further re-aeration in this lung was afforded. The patient was reported as indicating a benign tumor ultimately classified as a fibroma (Fig. 7).

On December 24, 1946 the thorax was opened by making an incision in the left lower rib cage and extracting the tumor from the upper reaches of the bronchial tree. It was found that both lobes were completely consolidated so that a pneumonectomy would have to be done. The safest form of resection. Since the tumor was benign by biopsy and in all probability pediculated

Fig. 5. Roentgenogram taken approximately 1 month after operation showing crystal atelectasis.

it was decided to explore its resectability by open bronchotomy. The lung was rotated forward and the bronchus dissected free. An incision was made into the posterior membranous portion longitudinally where the tumor was palpable. The tumor promptly herniated through this incision as if under pressure. The incision was carried distally following the course of the tumor down to a very narrow stalk from which it arose in the roof of the dorsal branch bronchus to the lower lobe. An area of mucosa was excised at the point of attachment of this stalk (Fig 3). Much purulent sputum was aspirated from the bronchial tree and all branches were cleaned as completely as possible by catheter suction. The bronchial incision was closed with interrupted silk sutures in one layer and the thorax was closed in routine manner with drainage by an anterior and posterior intercostal catheter.

The postoperative course was gratifyingly benign the lung progressively aerating and expanding to fill the hemithorax. The fever subsided as the retained secretions were coughed up. Five weeks following the operation, the chest was virtually normal by roentgenogram; there was surprisingly little evidence of bronchiectasis by bronchography; the bronchial lumen was normal on bronchoscopic examination except for a very small ridge at the site of suture and symptoms were rapidly disappearing. The only postoperative complication was the presence of a mild jaundice of undetermined etiology (Figs 4, 5 and 6).

Fig. 6. Bronchogram approximately 1 month postoperative. Although changes are seen in this bronchial tree they are not very advanced. Cough was rapidly abating and sputum as being raised only in small and decreasing amounts.

Fig. 7. Histologic appearance of the tumor. After differential staining this tumor was considered as being in the fibrocytic class rather than of smooth muscle origin. Diagnosis fibroma. (Courtesy of Dr. W. L. McNamara, Veterans Administration Hospital, Hines, Illinois)

When compared to the case reported by Bloesser certain differences are noted. In his case the history was one of intermittent bronchial obstruction over a period of 4 to 5 years; there had occurred a suppurative complication requiring surgical drainage from which a bronchocutaneous fistula had apparently persisted; the tumor was not visualized even by repeated bronchoscopic examinations; the neoplasm was ultimately classed as a carcinoma and finally from the standpoint of technique the bronchus was incised transversely and this incision later extended.

In our case the clinical and roentgenologic data indicated a progressive type of bronchial obstruction of relatively short duration (9 to 10 months) and there had been no suppurative complication requiring surgical drainage; the benign character of the tumor and the level of the obstruction was well understood preoperatively and finally the bronchus was incised longitudinally.

Certain points in technique may be worth recording:

1. The position of the patient on the table seems to be of importance and the use of the face down position as described by Overholt so disposes the hilum that the long axis of the bronchus is accessible in a roughly horizontal manner for ease of surgical manipulation. It further tends to favor the displacement of the lung in such a way that the main

lobar branches of the bronchial tree are relatively dependent from the main stem bronchus thereby making control of the retained secretions easier.

The bronchus is cleared over a sufficient length of its course to insure adequate room. It was steadied in our case by a proximal and distal loop of umbilical tape. The use of stay sutures as mentioned by Floesser seems to carry the possibility of incorporating the tumor as well as the bronchial wall in one or both of them. In our dissection of the bronchus no particular attention was paid to the boundaries of the mediastinum, our intention being rather to clear an adequate length of the bronchus as determined by palpation of the tumor.

3 The mediastinum was not closed by suture but was thus allowed free drainage into the pleura.

4 A longitudinal incision in the bronchus seems to offer the best possible exposure and affords an incision that is easily reparable.

5 Ample drainage of the pleura should be provided because these lungs are all probably low in expanding and the hazard of empyema would seem to be thereby lessened.

In our case the lung re-expanded steadily but slowly and the fear that the pleural fluid

may have become organized was overcome (Fig. 4). However this possibility did not materialize.

Antibiotics and chemotherapy both orally and intrapleurally were used rarely. The drains were removed only when they had ceased to function.

SUMMARY

1 A case is reported in which a pedunculated intrabronchial tumor (E—) was managed by posterior transpleural thorotomy with excellent results.

2 A general discussion of the posterior transpleural surgical approach is presented and a few technical considerations derived from the experience in this case are pointed out.

LARYNGECTOMY

LOUIS H. CLERF, M.D., F.A.C.S., Philadelphia, Pennsylvania

IN the treatment of carcinoma of the larynx the only hope of survival for the patient lies in complete eradication of the growth. In determining the method of treatment one must bear in mind that untreated cancer is a fatal disease; that the saving of life is the primary consideration of therapy; and that voice impairment or loss of the larynx is of secondary importance.

That eradication of carcinoma can be accomplished in selected cases by laryngofissure has been amply demonstrated by reports in medical literature and a personal experience of 173 cases, of which 188 patients were treated 5 or more years ago. It also has been shown that in certain cases satisfactory results can be secured by irradiation. Viewing the subject purely in the abstract, however, there can be no question that laryngectomy offers a greater degree of security from a life expectancy standpoint than laryngofissure or irradiation therapy but there is much greater disability.

Surgeons are agreed that as a rule one chance is given to cure a patient with carcinoma; this applies definitely to carcinoma of the larynx. Patients and many physicians are of the opinion that there can be a choice between irradiation and conservative or radical surgical treatment with end results about equal irrespective of the laryngeal lesion. There must be definite indications for these therapeutic measures if patients with carcinoma of the larynx are to survive. If one inclines too much to the side of conservatism, influenced by the patient or his family to save the larynx, or lacks the courage to do a more radical operation, the patient often will pay with his life. I cannot agree with those who believe that laryngectomy still can be performed and good results obtained if there is recurrence of the carcinoma following laryngofissure or irradiation therapy. My statistics indicate that in these metastasis to regional lymph nodes is of common occurrence and

that laryngectomy performed as a secondary procedure frequently proves inadequate. It again emphasizes that whoever treats the patient first has the best chance to get him well.

In my experience the most common cause of failure was an inaccurate estimate of the true extent of the carcinoma. It often is difficult to determine the extent even of early carcinoma. In a study of 188 cases of presumably early carcinomas treated by laryngofissure 5 or more years ago, metastasis to regional lymph nodes or distant structures occurred in 12 cases and local recurrence in the larynx in 27. In checking the location of the primary carcinoma in the 27 cases of local recurrence all were found to have involved either the anterior commissure or the subglottic area. It is evident that laryngectomy should have been the primary surgical procedure in these cases. It is of interest to note that local recurrence after laryngofissure was observed more than twice as often as metastasis to regional lymph nodes or distant organs; local recurrence is uncommon if an orthodox laryngectomy has been performed.

INDICATIONS

The indications for laryngectomy have often been discussed and should be well understood. In selecting the method of treatment the criteria to be considered are the extent and location of the growth, disturbances in motility of a vocal cord or arytenoid, the grade of malignancy, the presence or absence of metastasis, and finally the condition of the patient. Determination of the primary location and extent of the growth should be relatively easy since practically all laryngeal carcinomas are of the squamous cell variety and therefore are surface growths. In addition a majority primarily involve the anterior one half of a vocal cord, commonly extend forward and downward and should be readily visualized by either mirror or direct laryngoscopy. In spite of this however it has been the experience of all laryngologists that the extent of the

From the Department of Laryngology and Broncho-Esophagology, Jefferson Hospital.

Fig. 1. Photomicrograph from laryngectomy specimen case of cordal carcinoma that basically appeared as an early superficial lesion. Clumps of epibell cells were found infiltrating the cricothyroid muscle, a part of which had been removed at the time of operation. $\times 25$.

less than usually is greater than appears on the surface. I often have been impressed with Mackenty's statement that it is wise to add two thirds to the visible portion of the growth in estimating its actual size.

In addition to determining the extent of the surface involvement it is important to recall that submucosal extension continues beyond surface margins. New and Fletcher studied a group of cases of carcinoma and found that with the exception of grade 1 carcinoma there was extension of the growth varying from a few millimeters to as much as 15 millimeters from its apparent margins. The average extension of all grades of carcinoma was 5.5 millimeters.

My experience with lesions in the anterior commissure has shown that in spite of treatment by a radical form of laryngohisture consisting of removal of a triangular segment of the thyroid cartilage together with portions of both vocal cords and an apparently adequate margin of surrounding normal tissue results have been unfavorable (3). Recurrences have been more common in this group than in any other. In spite of the scant lymphatic drainage in the anterior larynx. It is possible that

Fig. 2. The larynx has been skeletonized. A traction on the hyoid bone the margin of the epiglottis is visualized. Before the pleary is opened. A suture on a continuous needle then is passed through the mucosa and fascia between the epiglottis and base of the tongue as shown in the illustration. When this is tied the tissue is gathered. A triangle is then made through the mucosa, along the edge of the epiglottis (shown by dotted line) and separation continued along margins. The upper and lateral limits of the lesion then be formalized.

Broyles, who directed attention to the tendinous attachment of the anterior end of the vocal cord to the thyroid cartilage and the absence of a perichondrium has provided the explanation. Carcinoma in the anterior commissure may extend along this tendon to the cartilage without necessarily manifesting itself as a surface lesion in the anterior end of the cord. Involvement of cartilage is rarely suspected before operation and early involvement may manifest itself only by slight rounding of the cartilage. This normally occurs at the attachment of the cords anteriorly. There also may be extension of the growth to the side of the larynx corresponding to the cricothyroid membrane without demonstrable metastasis to the pretracheal lymph nodes. L.

Fig 3. With the tied chromic suture held taut and traction made on the hyoid bone the cut edges of the pharyngeal mucosa can be approximated by continuous suture as it is separated from the larynx.

Fig 4. This illustration shows closing of the pharyngeal stoma by continuous chromic suture. (This suture should be held taut by an assistant.) It is important that the raw surfaces and not the mucosa are approximated. With completion of this suture the cut edges of the inferior constrictor of the pharynx and its fascia are approximated and an additional third layer of interrupted sutures is placed to help obliterate the space. Complete skeletonizing down to the tracheal mucosa should be done before the airway is opened.

In addition the carcinoma may extend to the cricothyroid muscle yet appear as an early cordal lesion (Fig 1). New and Fletcher found that in 32 specimens in which carcinoma could be demonstrated inside the cartilage there were 11 in which the growth was also present outside the cartilage. I am convinced that if anterior commissure lesions are treated by laryngectomy there will be fewer recurrences in these cases. In the 27 cases of local recurrence of carcinoma in the larynx following laryngofissure it is fair to assume that complete removal of the primary lesion could have been secured by laryngectomy.

Subglottic carcinoma is diagnosed late as symptoms commonly do not manifest themselves until the lesion has extended to the vocal cords. In my earlier cases I believed that removal by laryngofissure was adequate. Subsequent developments have indicated con-

clusively that a more extensive removal should be carried out and in questionable cases a prophylactic block dissection of the neck be part of the primary operation. I agree with Orton that subglottic carcinoma of the larynx is best treated by laryngectomy.

Carcinoma of the epiglottis commonly begins near its base. It rarely is observed as a marginal lesion. These lesions too are commonly advanced before a diagnosis is made since the vocal cords practically never are involved. Symptoms are meager and the lesion often is overlooked even by laryngologists. There is a tendency for direct invasion of the pre-epiglottic space as the lymphatic drainage from the base of the epiglottis and the anterior extremity of the ventricular band is carried

across the space through the thyrohyoid membrane. (4) Conservative treatment therefore is inadequate and laryngectomy is recommended. III gives the best result.

Koentgen studies of the neck, particularly lateral view and tomogram, are of value to ascertain the extent of carcinoma, particularly in those cases in which one cannot visualize the ultimate portion of the growth. In order to have a soft tissue shadow appear on a roentgen film so that it can be recognized as abnormal it must be of considerable size and unfortunately in a diagnosis of carcinoma the size of a nodule size commonly are advanced. It is important that diagnostic aids be accorded their proper value. Mirror laryngoscopy with or without direct examination is still the best method to ascertain the location and extent of a lesion in the larynx.

On the basis of extent and location of the carcinoma I believe that all lesions confined to the larynx with the exception of those involving the anterior and middle third of a vocal cord without extension to the opposite side and without fixation of the cord should be treated by laryngectomy.

Fixation of an arytenoid indicates involvement of the aryepiglottoid joint and extension to the posterior or larynx. Fixation of a vocal cord is observed when there is infiltration of its musculature by carcinoma. This is a significant sign and I should suggest that conservative surgery probably will be inadequate.

While the grade of malignancy of a carcinoma should be considered in the selection of treatment I do not believe that it is as important as the foregoing. A majority of vocal cord and epiglottic tumors are of a low or intermediate grade of malignancy and undifferentiated carcinoma is not commonly observed. On the other hand carcinoma of a ventricular band or arytenoid frequently is undifferentiated in type.

Metastatic and extralaryngeal extension seriously influence the plan of therapy and the prognosis. I believe, however, it has been conclusively shown that the outlook is better if radical surgery is resorted to. Pre-epiglottic extension of carcinoma of the epiglottis has been successfully treated with radical surgical removal of the pre-epiglottic space and larynx-

gectomy. I consider this type of carcinoma favorable for surgical treatment if the primary lesion in the pyriform sinus or the interarytenoid area where metastases are early. Metastasis to the deep cervical nodes in the region of the bifurcation of the carotid artery complicating carcinoma of the vocal cord or epiglottis does not constitute a hopeless problem and better results are secured by block dissection and laryngectomy than by laryngectomy plus irradiation. In time I performed laryngectomy and block dissection as separate procedures. Since this has been done as a one stage procedure and in the first patient treated in this manner there has been no recurrence for more than 5½ years. I have done this operation a number of times since with excellent postoperative results as well as nonrecurrence of carcinoma although the eurytomy group have not elapsed. I believe therefore that the outlook of carcinoma of the larynx from a surgical standpoint is good. I further believe that if laryngectomy is performed more in preference to conservative surgical treatment in the borderline cases there will be fewer recurrences. In cases with metastases radical resection of the entire area together with removal of the primary lesion can be carried out with safety and the results will be far better than those secured by any one method or combination of methods.

Laryngectomy has been described as a formidable mutilating operation which leaves the patient an economic burden and a social logic wreck. In discussing the psychologic adjustment of laryngectomized patients Schall found them a cheerful and optimistic group who readily make readjustment. This has been the experience. A large number of these patients can be taught to talk and the remainder can have recourse to mechanical or electric devices. I have had but one patient who failed to adjust himself and I regretted his condition to have a laryngectomy. This is the problem therefore should be taken into consideration as a factor when it comes to the treatment.

DISCUSSION

The fundamental principle of the technique of laryngectomy remains unchanged.

The choice of anesthetics must be left to the individual operator. I prefer local anesthesia by infiltration supplemented by barbiturates for laryngectomy. In case block dissection and laryngectomy are required, inhalation anesthesia, preferably by intubation, is desirable. Variations in the technique of laryngectomy are necessary to meet certain requirements. Thyrotomy should be done if there is a question concerning laryngofissure or laryngotomy. Conservation of structures about the larynx, notably attachment of muscles, has I believe certain hazards and violates one of the primary principles of the surgical treatment of cancer. There is nothing to be gained by saving muscular attachments or even the ribbon muscles, and there always is a chance of retaining tissues that are the seat of metastatic carcinoma, notably in the pretracheal region. I therefore remove all of these routinely. In addition, a segment of hyoid bone is removed routinely. In invasion of the preepiglottic space the entire hyoid bone and the preepiglottic space are removed intact.

For a time I employed the Barretto clamp but have discontinued this during the past 16 months (8). My objection to it is that it prevents visualization of the lesion during the removal of the larynx and also requires that the trachea be amputated early in the operation since the larynx must be removed from below upward. I prefer to remove the larynx from above downward so that I can more clearly visualize the lesion in addition it lessens the hazards of aspiration of blood into the trachea. Since discontinuing the use of the clamp I have employed a technique which protects the wound from pharyngeal contamination and retains the laryngotracheal airway until near the completion of the operation. After the larynx is skeletonized and the mucosa of the epiglottis is freed along its lingual aspect, a No. 0 nontraumatic chromic suture is passed through the mucosa and fascia between the base of the tongue and the epiglottis (Fig. 2). When this suture is tied the pharynx is opened and with the suture held taut, it is possible to prevent contamination of the wound by secretions (Fig. 3). This procedure permits one to inspect the lesion particularly if there is a question of extension

laterally which often cannot be satisfactorily visualized in extensive lesions by mirror or direct laryngoscopy. Suturing of the mucosa of the pharynx can be carried out as its separation from the larynx proceeds so that at no time is there any danger of spilling over of secretions (Fig. 4). In addition the airway is protected and there is no aspiration of blood or mucus. Complete skeletonization of the larynx can be completed, the second layer of sutures corresponding to the pharyngeal constrictors can be placed and drainage tubes through an independent counter opening can be inserted before the larynx is amputated. If there is dyspnea a Flagg tube may be inserted at any time.

In subglottic extension particularly when there is stenosis of the larynx which cannot be traversed by direct laryngoscopy it is difficult to determine the level of amputation. To ascertain if the growth extends subglottically I employ a laryngeal mirror through the opening made between the cricoid cartilage and the first tracheal ring to secure a reflected image of the subglottic larynx. This has been helpful in many instances to determine whether the line of amputation should be continued at that level or whether one should remove one or more additional tracheal rings. When growths extend down to the level of the first tracheal ring the prognosis usually is hopeless because of metastasis along the party wall.

MORTALITY RATE

The postoperative mortality of laryngectomy is low and with antibiotics pulmonary complications are uncommon and primary healing is the rule. The most common cause of postoperative mortality is cardiovascular complications. In 326 cases of laryngectomy there was a postoperative mortality of 14 (4.3 per cent). Of these 6 died from pulmonary complications and 8 from coronary occlusions, cardiorenal disorders or apoplexy.

RESULTS

It is difficult to evaluate end results following laryngectomy unless one classifies cases according to anatomical location and extent of involvement. If the carcinoma is confined to the larynx and there is no metastasis to

across the space through the thyrohyoid membrane (4). Conservative treatment therefore is inadequate and laryngectomy a recommended. If I gives the best results.

Röntgen studies of the neck particularly lateral view and tomogram are of value to ascertain the extent of carcinoma particularly in those cases in which one cannot visualize the ultimate portion of the growth.

It is not to have a soft tissue shadow appear on a roentgen film so that it can be recognized as abnormal it must be of considerable size and unfortunately in a diagnosis of carcinoma lesion of considerable size commonly are advanced. It is important that diagnostic aids be accorded their proper value. Mirror laryngoscopy with or without direct examination still the best method to ascertain the location and extent of a lesion in the larynx.

On the basis of extent and location of the carcinoma I believe that all lesions confined to the larynx with the exception of those involving the anterior and middle thirds of a vocal cord without extension to the opposite side and without fixation of the cord should be treated by laryngectomy.

Fixation of an arytenoid indicates involvement of the aryarytenoid joint and extension to the posterior half of the larynx. Fixation of a vocal cord is observed when there is infiltration of the musculature by carcinoma. This is a significant sign and should suggest that conservative surgery probably will be inadequate.

While the grade of malignancy of a carcinoma should be considered in the selection of treatment I do not believe that it is as important as the foregoing. A majority of vocal cord and epiglottic tumors are of a low or intermediate grade of malignancy and undifferentiated carcinoma is not commonly observed. On the other hand carcinoma of a ventricular band or arytenoid frequently is undifferentiated in type.

Metastasis and extralaryngeal extension seriously influence the plan of therapy and the prognosis. I believe however it has been conclusively shown that the outlook is better if radical surgery is resorted to. The epiglottic extension of carcinoma of the epiglottis has been successfully treated with radical surgical removal of the pre-epiglottic space and larynx.

I consider this type favorable for surgical treatment. A primary lesion in the pyriform interarytenoid area where metastasis is to the deep nodes in the region of the bifurcated carotid artery complicating a vocal cord or epiglottitis does not constitute a hopeless problem and better secured by block dissection and I than by laryngectomy plus irradiation. I performed laryngectomy and block dissection as separate procedures. This has been done as a one stage operation and in the first patient treated in this manner there has been no recurrence for 3 1/2 years. I have done this operation a number of times since with excellent postoperative results as well as non-recurrence of carcinoma although the customary outlook of carcinoma of the larynx from a surgical standpoint is good. I further believe that if laryngectomy is performed in preference to conservative surgery in the borderline cases there are fewer recurrences. In cases with more extensive radical resection of the entire area with removal of the primary lesion is secured and the results are far better than those secured by any method or combination of methods.

Laryngectomy has been described as a mutilating operation which ruins the patient an economic ruin and a psychological wreck. In discussing the psychological aspect of laryngectomized patients Schall found them a cheerful and optimistic group who make readjustments. This has been the experience of a large number of these patients who can be taught to talk and the remainder can have recourse to mechanical or electronic devices. I have had but one patient who failed to adjust himself and I regretted that he must have a laryngectomy. This phase of the problem therefore should not be considered a factor when determining the proper treatment.

CONCLUSIONS

The fundamental principle is that if the patient is fit for laryngectomy, it should be performed.

THE EFFECT OF ABSORBABLE SPONGE MATERIALS ON THE ACTIVITY OF THROMBIN

JOHN H OLWIN M D and FREDERICK J WAHL, M D., Chicago Illinois

SINCE the isolation of thrombin for practical use by Seegers and his associates in 1938 (18 19 22) the interest in absorbable hemostatic agents has rapidly increased. The war lent impetus to the search for an absorbable sponge that might give the added advantage of the pressure factor in the control of hemorrhage difficult checked by ligature or the topical application of thrombin.

Of these absorbable sponge materials developed in recent years the 3 receiving the most study have been cellulose oxidized by nitrogen dioxide, gelatin and fibrin foam obtained by fractionation of human plasma.

Since these materials followed closely on the heels of thrombin and since thrombin is itself the most active clotter of blood or plasma known at the present time it is natural that they should be used clinically in conjunction with thrombin. They have also been used very effectively as hemostatic agents without the use of thrombin particularly oxidized cellulose and gelatin. This paper deals with the relationship of these three materials to thrombin.

Oxidized cellulose Yackel and Kenyon in 1942 reported the development of an oxidized cellulose which was readily soluble in dilute alkalies and which even with a high degree of oxidation remained fibrous and not friable. The degree of oxidation depending on the content of the carboxyl groups was readily controlled and hence the end product might be varied according to the need for a more or less soluble absorbable or pliable substance. Material containing less than 15 per cent carboxyl groups is not brittle and is easily handled without breaking up. It is slightly degraded by oxidation and may change from its

original white to an off white. It does not stand autoclaving but may be satisfactorily sterilized by formaldehyde. It withstands boiling for 3 minutes.

Frantz (6) placed oxidized cellulose in muscle brain dura joint and peritoneum of animals and found a minimum of tissue reaction. Absorption of the material varied between 10 days and 6 weeks being complete in all cases at the end of this time. The tissue reaction was more marked in the case of the more highly oxidized cellulose apparently because of the higher carboxyl content. In 2 instances the cellulose was soaked in thrombin before being buried in the brain and in these cases the tissue reaction was less than when the cellulose was used alone. Putnam found soluble cellulose dampened with thrombin an effective hemostatic agent. Cronkite Deaver and Lozner used oxidized cellulose with thrombin of both rabbit and human origin and found it effective as a hemostatic agent in both traumatic and elective surgery.

In 1944 Seegers and Doub (20) showed that oxidized cellulose having a carboxyl content of 14 per cent rapidly reduced the pH of a standard thrombin solution to below 4.3 the inactivation point of thrombin. They further showed that when this same cellulose was first soaked in a 1 per cent solution of bicarbonate of soda for a sufficient period of time the pH of the thrombin remained on the alkaline side and its activity was unaltered. They also found that when the oxidation of cellulose is carried further than is required for rapid absorption *in vivo* acidity remains a factor, but there are other products of oxidation which destroy thrombin. Cellulose having a carboxyl content of 21 per cent when first soaked in a 1 per cent solution of sodium bicarbonate did not alter the pH of thrombin but its activity when tested against a standardized fibrinogen solution had disappeared. The nature of the destruction is unknown.

From the Department of Surgery, Presbyterian Hospital of the City of Chicago affiliated with the University of Illinois College of Medicine.

This study was made possible by grant from the Otto S. A. Sprague Memorial Institute Fund.

gen and the conditions under which they are processed, a wide range of products may be obtained. At one extreme is the light fluffy foam that shrinks when wet to about 10 per cent of its dry volume. At the other extreme is a dense firm substance which shrinks only about 50 per cent when wet. Variations in elasticity and flexibility are also possible with variations in physical and chemical treatment. By varying the procedure of production a wide range of thrombic activity may be obtained thus providing for use as a hemostatic alone or in conjunction with a thrombin solution. The material may also be produced with varying fibrinolysin content and varying susceptibility to bacterial fibrinolysin so that its rate of absorption *in vivo* and *in vitro* may be controlled. The material so produced is sterile and does not stand boiling or autoclaving without change of mechanical properties. Bailey and Ingraham (11) implanted fibrin foam and oxidized cellulose soaked in thrombin under the dura of monkeys. They later found adhesions between the dura and arachnoid on the side in which the cellulose was placed. They found no difference in the degree of tissue reaction or the rate of absorption between the two substances.

Bailey and his associates (2) implanted fibrin foam and soluble cellulose both materials with and without thrombin in the liver peritoneal cavity, abdominal wall, kidney and lung of experimental animals. In all instances there was minimal tissue reaction and little difference in that elicited by the two substances. Both were absorbed in 5 weeks or less, the cellulose disappearing in a slightly shorter time than the fibrin foam. The hemostatic effect was satisfactory in all instances. In 240 general surgical cases fibrin foam and thrombin were effectively used as hemostatic agents.

Gelatin sponge. In 1945 Correll and Wise (3) reported the preparation of an absorbable water insoluble gelatin base sponge obtained by foaming a gelatin solution and drying it in special forms. It is white, tough, porous, non-elastic and may be cut into any desired size or shape. It will take on 50 times its weight of water and about 45 times its weight of blood. It was found to be nonantigenic.

Correll, Prentice and Wise (4) placed implants of gelatin sponge, fibrin foam and starch each soaked in thrombin into the muscles of rats. Each elicited a minimal tissue reaction. They found the gelatin sponge completely absorbed in 30 days, starch persisted through the 50th day after implantation and fibrin foam was not completely absorbed at the 100th day. Light and Prentice made similar comparisons on thrombin soaked implants of gelatin and fibrin foam placed deep into the brain subcortically, subdurally and as patches to repair torn venous sinuses. They found no appreciable difference in tissue reaction to the two types of sponge when implanted under similar conditions. Neither was there any difference in tissue reaction when human thrombin was substituted for the bovine product. Both the gelatin and fibrin foam patches effectively stopped the flow of blood from a torn venous sinus and there was no instance of a thrombus occurring in the sinus channel.

Gelatin sponges without thrombin were implanted into various animal tissue by Jenkins and Clarke (13). The tissue reaction was less than that elicited by cat gut and the material was absorbed in about 5 weeks. They found it to be an efficient hemostatic in its own right. Jenkins, Janda and Clarke (14) used it experimentally with and without thrombin and report a more rapid hemostasis when thrombin was used. The difference however was not marked. In comparing gelatin sponge with fibrin foam and oxidized cellulose they found the immediate hemostatic efficiency of the three about equal. The soluble cellulose however did not adhere so firmly to the tissue surface as did the gelatin and the fibrin foam was more easily broken up. Jenkins and Janda (15) made stab wounds in the large veins including the vena cava in dogs and in other instances excised a portion of the vein wall. They used gelatin sponge without thrombin as patches to cover the defects. In most instances the hemostasis was successful and the defects were closed by an endothelialized scar at the end of 3 weeks. After a month it was difficult to identify the sponge grossly. Again they demonstrated that gelatin sponge alone is an effective hemostatic agent though they

TABLE I.—EFFECT OF OXIDIZED CELLULOSE ON THE ACTIVITY OF BOVINE AND HUMAN THROMBIN

Substance	pH	Clotting time (seconds) after addition of 0.1 cc thrombin solution		Note
		Oxalated plasma, C.	5% Fibrinogen solution.	
Distilled water 60	6.05			
Fine thrombin (bovine) 500 units	7.04		3	0-25
		4	6	
Fine cellulose 500 gm	8.2	4	4	0-15
		6	4	
Fine cellulose 12 gm. (total 512 gm.)	8.67	No clot after 3 minutes	No clot after 3 minutes	0-30

The pH of the thrombin is rapidly reduced to below its inactivation point on the addition of a total of 254 gm. of oxidized cellulose about 1/5 the amount packaged by the manufacturer. Note that the thrombin is still active after 0.1 gm. of cellulose has been added and the pH is still above the inactivation level of thrombin. The amount of cellulose is less than that likely to be used clinically for hemostatic in most instances. The compatibility of smaller amounts of cellulose and larger amounts of thrombin was not investigated.

believe that the addition of thrombin enhances and accelerates the hemostatic action

EXPERIMENTAL STUDY

In view of the increasing use of absorbable sponge materials in many instances in conjunction with thrombin it seemed of interest and importance to investigate the effects of the various substances on the activity of thrombin. Included in this study are absorbable cellulose fibrin foam and gelatin used with human and bovine thrombin as described below. Quantities of each substance were in general kept within limits likely to be used clinically for hemostasis. No attempt was made to investigate the extreme limits of compatibility of the substances.

Thrombin human and bovine in varying unitages was dissolved in both distilled water and normal saline solution. The pH of each solvent was measured by means of the glass electrode before and after the addition of the thrombin and at various stages after the addition of the soluble sponge material. The activity of the various thrombin solutions was determined by adding 0.1 cubic centimeter of the particular solution to 0.1 cubic centimeter of standardized fibrinogen solution and

TABLE II.—EFFECT OF OXIDIZED CELLULOSE ON THE ACTIVITY OF BOVINE AND HUMAN THROMBIN

Substance	pH	Clotting time (seconds) after addition of thrombin solution		Note
		Oxalated plasma, C.	5% Fibrinogen solution, C.S.	
Normal saline 60 C.C.	7.89			
Fine thrombin (bovine) 500 units	6.92	37	87	
		16.4	8	
Fine cellulose 0.375 gm.	4.57	64.9	No clot after 3 minutes	12-30
		76.8		
Fine cellulose 275 gm. (total 350 gm.)	3.06	No clot after 3 minutes	No clot after 3 minutes	

In this instance the pH of the thrombin solution was reduced to below its point of inactivation after the addition of 350 gm. of cellulose.

checking the clotting time. Similar tests were made in each instance freshly collected oxalated human plasma being used in the same quantities. The prothrombin in the plasma was rendered inactive by the oxalate, but the fibrinogen was still available for reaction with thrombin.

Various absorbable sponge materials in weighed amounts were added to the respective thrombin solutions and the pH and activity of the solutions measured after each such addition. The time factor was also taken into account. As a rule sponge samples were added until there was little or no further change in the pH of the thrombin solution, and in many instances no further change in the activity of the thrombin. Most experiments were completed within a 2 hour period though in a number of instances the thrombin, when its activity was little affected by the sponge, was stored at approximately 5 degrees centigrade, and its activity followed at intervals for as long as 47 days. No attempt was made to keep the solutions sterile.

In the case of oxidized cellulose various reagents were used in an attempt to neutralize its acid character among these being sodium bicarbonate sodium oxalate, sodium citrate, sodium acetate imidazole and glycerin. The cellulose was soaked in these solutions for varying periods of time before being placed in the thrombin solution.

TABLE III.—EFFECT OF BUFFERING ACTION OF 1 PER CENT DICARBONATE OF SODA ON THE ACID NATURE OF OXIDIZED CELLULOSE

Substance	pH	Clotting time (seconds) after addition of 1 c. thrombin solution	Time
		Oxalated plasma, 0.1 c.c.	1% Fibrinogen solution, 0.1 c.c.
Normal saline 60 p.p.	5.80		
Fine thrombin (bovine) 500 units	6.45	3.4	9.3
		9	0
			9.9
Fine cellulose 777 gm.	4.04	33.0	35.6
		45.5	39.8
		56.0	37.7
Fine cellulose 710 gm.	3.5	0.5	N clot after 3 minutes
		8.1	
Fine cellulose 814 gm. (total 830 gm.)	3.35	N clot after 3 minutes	

Each sample of cellulose was soaked for 1 minute in 1 per cent solution of bicarbonate of soda before being added to the thrombin solution. Note that though considerably delayed, clotting of the plasma does take place after the pH of the thrombin has dropped to 3.5, well below the point of inactivation of thrombin. This would indicate that the inactivation is not immediately irreversible and as shown here the natural best-where action of the plasma has been sufficient to raise the pH to a point where some activity of the thrombin has been restored. The fibrinogen solution is not buffered hence the thrombin solution remains inactive on contact with it.

RESULTS

Oxidized cellulose in small amounts when added to thrombin solutions of varying strengths and volumes reduced the pH to the inactivation level or below within a few minutes. These thrombin solutions were highly active before the addition of the cellulose and became inactive when the pH dropped to below 4.3. This was true in the case of both the bovine and human thrombin and when put in to solutions of either distilled water or normal saline. Typical reactions are shown in Tables I and II. If cellulose was first soaked in a 1 per cent solution of sodium bicarbonate for 30 seconds before being added to the thrombin solution similar results were obtained. The pH of the thrombin dropped rapidly and the thrombin became inactive. When this buffering time was increased to one minute there were varying effects. In all instances there was a lowering of the pH value of the thrombin but usually not below its point of inactivation. In other instances the pH dropped to below

TABLE IV.—EFFECT OF BUFFERING ACTION OF 1 PER CENT DICARBONATE OF SODA ON THE ACID NATURE OF OXIDIZED CELLULOSE

Substance	pH	Clotting time (seconds) after addition of 0.1 c.c. thrombin solution	Time
		Oxalated plasma, c.	1% Fibrinogen solution, c.c.

Fine cellulose 774 gm.	5.7		5
			6.2
Fine cellulose 718 gm.	5.3	6	3.8
		5.8	5.4
Fine cellulose 718 gm. (total 830 gm.)	4.85	6.2	30.5
		6.8	3.7
	4.54	7.4	34.3
		17.4	34.6
	4.3	4	3.5
		6	3.3

Each sample of cellulose was soaked for one minute in 1 per cent bicarbonate of soda solution before being added to the thrombin solution. The pH of the thrombin solution was reduced by the buffered cellulose but still active after the addition of 830 gm. of the material.

this point. The activity of the thrombin was diminished in all instances and followed in degree for the most part the pH values. Tables III and IV show two representative reactions. Leaving the cellulose in the buffering solution longer (total of 5 minutes) materially slowed the reduction in pH of the thrombin solution but the activity of the latter was still reduced (Table V). This supports the work of Seegers and Doub (20) who found an unexplained factor other than a reduction of the pH value by which cellulose having a carboxyl content of 21 per cent interfered with the activity of thrombin. The cellulose in this study had a carboxyl content of 18.5 per cent.

However oxidized cellulose soaked in the 1 per cent bicarbonate solution for as short a time as 1 minute began to disintegrate and was not well suited to packing into a wound. It assumed an amorphous jelly-like mass that broke up with handling. Dissolving the dry thrombin in a 1 per cent solution of sodium bicarbonate achieved the desired buffering effect but the oxidized cellulose soaked in it

TABLE V—EFFECT OF ADEQUATELY BUFFERED CELLULOSE ON THE ACTIVITY OF THROMBIN

Substance	pH	Clotting time (seconds) after addition of thrombin solution		Hour
		Oxalated plasma	% Fibrinogen solution	
Distilled water 60	6.05			
Fibrin thrombin (bovine) 5000 units	6.0	3	6	975
		3	4	
Fibrin cellulose 273 gm.	7		13	9130
			0.5	
			10	
Fibrin cellulose 274 gm.	7	30	14	9700
			14	
			5	
Fibrin cellulose 275 gm.	6.90	30.6	14	9030
		30		
		30	30.4	
Fibrin cellulose 280 gm. (total 18 gm.)		No clot after 3 minutes	No clot after 3 minutes	100

Each sample of cellulose was soaked in 1 per cent solution of bicarbonate of soda for 5 minutes before being added to the thrombin solution. The cellulose, as adequately buffered in this instance and the pH of the thrombin solution little affected. Despite this the activity of the thrombin declined and finally disappeared after the addition of 13 gm. of cellulose. This supports the work of Rogers and Douth (26) who found an unexplained factor other than the reduction of the pH value, by which cellulose having a carbonyl content of 21 per cent interfered with the activity of thrombin. The cellulose used in this instance had a carbonyl content of 6.5 per cent.

rapidly assumed the same jellylike consistency and was poorly suited to packing.

In an attempt to find another buffer that would not so readily dissolve the cellulose, samples of the material were added to solutions of sodium citrate sodium oxalate sodium acetate and glycerin. The buffering action of the citrate was about the same as that of the bicarbonate, and that of the oxalate, acetate and glycerin considerably less. In all instances however the cellulose began to dissolve within 3 minutes of the time it was added to the buffer. Imidazole a buffer used successfully in certain processes involving blood clotting because it does not precipitate calcium salts, was investigated. Its buffering qualities were better than those of any of the above substances, but the cellulose dissolved as rapidly in it as in the other solutions.

Fibrin foam. When fibrin foam was added to a solution of human thrombin in distilled

water or normal saline, there was a slight lowering of the pH value of the thrombin (Tables VI and VII). The activity was also slightly reduced though the change in both the pH and thrombin action was so minimal as to be of no clinical significance. As more fibrin foam was added to the same thrombin solution, the pH was further lowered and the thrombin activity changed accordingly. The changes after the addition of up to twice the amount usually packaged with one thrombin sample were still so slight as not to impair materially the usefulness of the solution clinically. If such solutions of thrombin were stored at 5 degrees centigrade with the fibrin foam still present in the solution, the thrombin activity remained little changed for from 8 to 12 days. After that, though the pH values were not further lowered but in fact came up slightly the thrombin activity continued to decline. One sample which clotted the fibrinogen solution at 6.4 seconds originally gave a clotting time of 33 seconds after 37 days (Table VII). This represents a fair degree of thrombin activity. Plasma that was originally clotted at 9.5 seconds by the same thrombin solution gave an average clotting time of 21 seconds after the thrombin had been stored for 38 days (Table VII). This apparent higher degree of activity of the fibrinogen in the plasma may be on the basis of the buffering action of the plasma. The fibrinogen solution did not contain a buffer.

Gelatin sponge. When gelatin sponge was added to bovine thrombin in either normal saline or distilled water the pH value of the solution was lowered. This occurred to a greater degree than when fibrin foam was added to thrombin but the pH level in all instances in this study was well above the inactivation point of thrombin. Even though the gelatin reduced the pH of thrombin more than did the fibrin foam, the resulting thrombin activity was much the same. Tables VIII and IX are representative of the changes in pH values and thrombin action when gelatin sponge is added to thrombin solution. When stored at 5 degrees centigrade with the gelatin still in the solution of thrombin, the activity of that solution remained fairly uniform over a period of 4 to 17 days with an average of 13 days. The μ m of the thrombin was slightly reduced by the addition of fibrin foam, but after the addition of a total of 335 gm. of the latter, fair degree of thrombin activity remained for as long as 36 days.

In this instance total of 34 gm. of fibrin foam affected the μ m of the thrombin slightly and the thrombin activity was not greatly reduced after 34 days.

In this instance 445 gm. of gelatin reduced the pc of thrombin to about the same degree as did 710 gm. (Table VIII), but the activity of the thrombin was reduced to a slightly greater degree on 11 days. In neither instance was the change of clinical significance.

most instances two to four times as much gelatin was added to the thrombin solution as is packaged with it by the manufacturers. Thus the possibility of any significant change in the activity of thrombin brought about by the usual amount of gelatin used is remote.

COMMENT

From this study it would appear that the use of thrombin with oxidized cellulose is a questionable procedure and may be contraindicated. Unbuffered cellulose in small amounts by virtue of its acid nature, rapidly lowers the pH of thrombin and thus inactivates it. Cellulose may be properly buffered so that it does not alter the pH of thrombin to any great degree but if the carboxyl content is sufficiently high, the thrombin is still inactivated by a factor in the cellulose as yet unknown.

Inasmuch as cellulose alone is a satisfactory hemostatic agent (8-9-17) and the acid nature of the material may be responsible for a certain degree of this hemostatic quality it is likely that the thrombin by partially neutralizing it may impair its value as a hemostatic agent.

The finding by Frantz and Lattes (9) that dry cellulose placed at the site of a clean fracture delays the formation of callus would suggest that the unbuffered material should not be used in open fractures or in bone surgery where callus formation is desired. How much of a rôle the acid factor plays in the inhibition of callus formation and how much may be due to other factors is speculative. It is suggested that in conditions in which the formation of new bone is undesirable as in fenestration of the wall of the inner ear and in certain arthroplasties the use of cellulose might be of value in discouraging callus formation. It is suggested that variations in the percentage of carboxyl content of the cellulose might be of value in such conditions thus providing different degrees of acidity and different absorption times of cellulose.

The use of buffering agents in our study was unsatisfactory because of the early disintegration of the cellulose in such solutions.

Fibrin foam and gelatin affected the activity of thrombin only slightly and solutions con-

taining these sponge materials remained active over a period of days. It is suggested that thrombin solutions made up for use in surgical procedures may be preserved at domestic refrigerator temperatures and in sterile condition for repeated use with fibrin foam and gelatin. Such solutions may be easily tested for thrombic activity by adding a few drops of the solution in question to a similar amount of citrated or oxalated blood. Such blood may be fresh or may be drawn from any bottle of bank blood suitable for transfusion. Blood not more than 3 weeks old should be satisfactory. The clotting of such thrombin blood combinations in 25 seconds or less indicates a thrombic activity considerably greater than that of the normal spilled blood and satisfactory for clinical use.

SUMMARY AND CONCLUSIONS

1. Oxidized cellulose because of its extreme acid character rapidly reduces the pH of thrombin to below its point of inactivation—4.3.

2. This acid character may be neutralized by first soaking the cellulose in a buffering solution of 1 per cent bicarbonate of soda. In this study soaking the cellulose for as short a time as 1 minute minimum time required for such neutralization, resulted in a disintegration of the cellulose to such degree that it was poorly suited to packing into a wound.

3. Other buffering agents including sodium oxalate, sodium citrate sodium acetate glycerin and imidazole caused similar disintegration of cellulose. Thrombin dissolved directly in 1 per cent sodium bicarbonate gave similar results.

4. Oxidized cellulose having relatively high carboxyl content, properly buffered by bicarbonate of soda solution does not reduce the pH of thrombin materially, but the activity of the latter is still impaired by a factor as yet unknown.

5. Because of these factors the use of thrombin in conjunction with oxidized cellulose for hemostasis is considered a questionable procedure.

6. Fibrin foam when added to thrombin dissolved in either normal saline or distilled water reduced the pH of the thrombin slightly but the reduction of neither the pH nor the throm-

bic activity was of sufficient degree to be of clinical significance. Such thrombin solutions when stored at 5 degrees centigrade retained sufficient activity for clinical use for an average period of 17 days and in some instances showed a fair degree of activity after 38 days.

7. Gelatin sponge when added to thrombin solution diminished the pH of that solution to greater degree than did fibrin foam though the thrombic activity was impaired to about the same degree. When stored at 5 degrees centigrade samples of such thrombin solution remained sufficiently active for clinical use for an average period of 13 days and in some instances were comparatively active after 37 days.

8. Solutions of thrombin made up for use at the operating table may be preserved at ordinary domestic refrigerator temperatures, in sterile condition and used over a period of days. The thrombic activity of such solutions is easily tested at the time of use by adding a small sample of it to citrated or oxalated blood.

OPPONENS TRANSPLANT AN ANALYSIS OF THE METHODS EMPLOYED AND RESULTS OBTAINED IN SEVENTY-FIVE CASES

JOHN W KIRKLIN M.D., Rochester Minnesota, and COLIN C THOMAS Jr M.D
Iowa City Iowa

THE opposable thumb constitutes one of man's most useful attributes. It is then of utmost importance to consider means of restoring opposition to thumbs deprived of it by injury to nerves or by direct loss of muscle.

It is the purpose of this paper to review our experience with tendon transfer for restoration of opposition in 84 cases of wounds of the upper extremities incurred in World War II in 75 of which sufficient data were available to permit analysis. The fundamental principles of this procedure have been brought out by Bunnell and others (3), and need not be elaborated herein.

INDICATIONS FOR OPONENS TRANSPLANT

The obvious indication for opponens transplant is lack of ability successfully to use the thumb, because of loss of its active opposition and abduction. Some individuals with relatively poor abduction and opposition of the thumb can still use their hand gainfully and do not desire reconstructive surgery. Others with a similarly functioning thumb feel handicapped by it in their particular type of work and therefore are in need of reconstruction. It is, then, a problem demanding not only an objective examination of the affected hand but concomitant consideration of the type of work which the patient must do with his hands.

In general, it can be stated that loss of ability to abduct the thumb to a distance of at least 1 inch (2.5 cm) from the palm with the tip of the thumb over the distal end of the third metacarpal bone, constitutes a fairly serious disability. This is particularly true when there is combined with this, a lack of ability to rotate the thumb and to bring it

across the palm so as to touch the tip of the little finger.

Individuals with complete paralysis of all the intrinsic muscles of the hand such as results from damage to both the median and ulnar nerves are in nearly all instances in need of opponens transplant. Roughly however 65 per cent of patients with paralysis only of the median innervated intrinsic muscles substitute adequately although in varying degrees of completeness for loss of the opponens pollicis and abductor pollicis brevis muscles by means of the flexor pollicis brevis in combination with the abductor pollicis longus (Fig 1). The remaining 35 per cent will require such a transplant in most instances.

These statements are based on our experience and that of others (2) that, in contrast to the median innervated long flexors the opponens pollicis and abductor pollicis brevis show actual return of motor function in only a small percentage of cases. This is true whether the injury to the median nerve has been incomplete and not requiring suture, or whether satisfactory neurotaphy has been carried out. Most of the 84 cases concerned herein were thus derived from the 618 cases of injury to the median nerve, some isolated and some combined with lesions of the ulnar nerve, seen among 3,276 injuries to peripheral nerves treated and studied in this neurosurgical center. The remainder were those in which there had been direct damage to musculature in the thenar eminence.

PREREQUISITES FOR SUCCESSFUL OPONENS TRANSPLANT

The prerequisites for successful opponens transplant are a relatively loose and supple hand the thumb of which can be brought passively into abduction rotation and oppo-

Work done in the Neurosurgical Section, O'Reilly General Hospital, Springfield, Missouri.

sition a suitable motor power to utilize in transfer and a hand in such condition that it will be functionally improved by this procedure.

In the hand in which the thumb can be brought passively into the desired position with ease, there exists little problem and the results of transplant are excellent. In wounds of the upper extremities of such severity as to cause injury to peripheral nerves, however there may have developed varying degrees of stiffness and fixed deformity of the hand. Such deformities never should be allowed to develop but if once developed they must be overcome prior to opponens transplant. By far the most important individual in overcoming these deformities is the patient himself. He must be made to understand thoroughly that his own constant working with the hand will improve it faster and more completely than will any other factor. Periods of work in a gainful occupation are unsurpassed as a means of obtaining this end. Proper splinting with constant gentle traction by an apparatus so designed as to pull the thumb into abduction and opposition is an adjunct, but only an adjunct to this active use of the hand.

The demand for an adequate motor power necessitates a musculotendinous unit in the forearm with sufficient strength to bring about opposition abduction and rotation of the thumb when the transplant has been properly completed without sacrifice of useful function in the remainder of the hand. When only the intrinsic muscles of the hand are involved in the paralysis there are of course a number of flexor tendons available. In injuries to the median and ulnar nerves in the upper arm in which there has been paralysis of the long flexor muscles, the surgeon should wait, after neurography until reinnervation of these muscles has proceeded to such a point that they have strength adequate for useful function when transferred. Occasionally in cases of extensive damage to soft tissues involving the flexor tendons the extensor carpi ulnaris proves to be the only available tendon when utilized, it functions satisfactorily as a transplant.

It has been pointed out that a third prerequisite for this operation is a hand in such condition that it would be functionally im-

proved by an opposable thumb. Sensation must be present in the hand, particularly in the thumb and in the index and long finger. Furthermore, there must be sufficient power in the fingers themselves to make them of value along with the thumb. In a few individuals, particularly those in whom all four fingers flex in a mass as a result of tendon damage or a previous tendon transfer to the flexors of the fingers, the thumb is probably better utilized in adduction, in which it can perform a pincers type of action against the radial aspect of the proximal phalanx of the index finger. It is, then important to emphasize again the necessity of accurately ascertaining whether the over-all usefulness of the hand will be improved by the new action of the thumb.

Although the absolute prerequisites for the procedure have been enumerated there are other features which are desirable. It is, of course advantageous to have relatively normal subcutaneous tissue for the rerouting of the transplanted tendons. This necessitates, in certain instances, the preliminary covering of the volar surface of the wrist and forearm with transplanted full thickness skin by means of abdominal flaps or tubed pedicles. Occasionally the use of a pre-formed sheath, as has been suggested by Milgram and others, will tend to diminish the tendency for adherence of the transferred tendon to surrounding structures. We have employed this in only a case, and thus our experience is too limited to allow an appraisal of its value in opponens transplant. It is also desirable to have a strong action in the flexor pollicis longus tendon and reinforcement of this, if weak, at the time of opponens transplant is usually of value.

CHOICE OF OPERATIVE PROCEDURES

There are two main types of operative procedures which have been employed in this group of cases. One is the Bunnell type of opponens transfer the second is the Thompson type. The Bunnell procedure (1) involves the use of a motor tendon rerouted on the proximal side of the transverse carpal ligament and so transferred and attached to the thumb that the line of pull on the thumb is directed toward the pisiform bone. A pulley in the region of

the pisiform bone is usually employed. In the Thompson procedure, a sublimis tendon, preferably that to the ring finger is severed with in the flexor tendon sheath in the finger, rerouted on the distal side of the transverse carpal ligament, and inserted both proximal and distal to the metacarpophalangeal joint of the thumb. In this instance the palmar fascia, around which the tendon is rerouted, acts after a fashion as a pulley.

The Bunnell procedure was used in all instances possible. However in not a few of our cases, there was found extensive scarring in the volar surface of the distal third of the forearm. In such individuals with marked forearm scarring and a normal palm we felt that the Thompson procedure was advisable. By employing this we were able to do all our transferring in normal tissue, and we thus avoided entering scarred areas.

Within the large group of transfers which follow the Bunnell principle, there are several useful variations. The basis of one group of these is the use of the extensor pollicis brevis as a means of prolonging the motor power employed. Such motor power can be supplied by means of the palmaris longus (Fig. 2) the flexor carpi ulnaris (Fig. 3) any one of the sublimis tendons or even by the extensor carpi ulnaris. As will be noted however the extensor pollicis brevis is not always suitable for use.

A second group involves the use of a free tendon graft to prolong the motor power. Such a tendon graft can be inserted into the dorsal and proximal aspects of the proximal phalanx of the thumb and then rerouted subcutaneously toward the pisiform bone. A third subdivision within the Bunnell type is a procedure which we have come to consider very satisfactory namely the use of a sublimis tendon preferably that to the ring finger without the use of an intermediary graft. In this type of operation the sublimis tendon is severed within the flexor tendon sheath of the finger very close to its point of insertion and then is withdrawn well proximal to the transverse carpal ligament. It is then rerouted in the manner illustrated (Fig. 4), and is inserted at the proper tension into a drill hole on the dorsal aspect of the proximal phalanx of the

thumb in most instances. In a few cases, for reasons which will be discussed subsequently it has been inserted into the distal end of the metacarpal bone.

TECHNICAL DETAILS OF OPERATIVE PROCEDURES

It is the purpose of this section to point out certain technical factors which seem to improve the results of opponens transplant. The principles common to all tendon transfer procedures will not be repeated but they are none the less of great importance. These include the use of a tourniquet, rigid adherence to aseptic precautions and care in the rerouting of tendons. Proper, moderate tension on the complete transfer also must be obtained.

The placing of the incisions in the skin is an easily controlled factor which is of importance. It is always advisable, of course, to make incisions along skin tension lines, whenever possible. However it has seemed in these cases even more desirable to so fashion these short incisions that they do not directly overlie tendons after rerouting or particularly, the site of anastomosis of tendons. A few of the incisions employed in this group of cases are indicated in Figures 5 and 6.

In rerouting tendons from the pisiform bone across the palm up into the incision in the thumb the finding of the proper plane for transfer is of great importance. This plane lies just superficial to the palmar fascia, and should be deep enough in respect to the skin itself so that the tendon does not become adherent to the overlying skin or so that pressure necrosis of the skin does not develop. This plane can be found by the passing of a long slim instrument such as a uterine packing forceps from the incision at the wrist, across the palm, and into the incision in the thumb.

When the extensor pollicis brevis is used as a means of prolonging the motor power a few technical details are of some importance. First are accurate location and recognition of this tendon. In a few individuals the tendon is nonexistent. If it is present, it must be dissected out in such a manner that when it is pulled upon in the direction of the pisiform bone it produces satisfactory opposition of the thumb. If it is dissected too far distally

ation a suitable motor power to utilize in transfer and a hand in such condition that it will be functionally improved by this procedure.

In the hand in which the thumb can be brought passively into the desired position with ease, there exists little problem and the results of transplant are excellent. In wounds of the upper extremities of such severity as to cause injury to peripheral nerves however there may have developed varying degrees of stiffness and fixed deformity of the hand. Such deformities never should be allowed to develop but if once developed they must be overcome prior to opponens transplant. By far the most important individual in overcoming these deformities is the patient himself. He must be made to understand thoroughly that his own constant working with the hand will improve it faster and more completely than will any other factor. Periods of work in a gainful occupation are unsurpassed as a means of obtaining this end. Proper splinting with constant gentle traction by an apparatus so designed as to pull the thumb into abduction and opposition is an adjunct but only an adjunct to this active use of the hand.

The demand for an adequate motor power necessitates a musculotendinous unit in the forearm with sufficient strength to bring about opposition abduction and rotation of the thumb when the transplant has been properly completed without sacrifice of useful function in the remainder of the hand. When only the intrinsic muscles of the hand are involved in the paralysis, there are of course a number of flexor tendons available. In injuries to the median and ulnar nerves in the upper arm in which there has been paralysis of the long flexor muscles, the surgeon should wait after neurography until reinnervation of these muscles has proceeded to such a point that they have strength adequate for useful function when transferred. Occasionally in cases of extensive damage to soft tissues involving the flexor tendons, the extensor carpi ulnaris proves to be the only available tendon when utilized it functions satisfactorily as a transplant.

It has been pointed out that a third prerequisite for this operation is a hand in such condition that it would be functionally im-

proved by an opposable thumb. Sensation must be present in the hand particularly in the thumb and in the index and long fingers. Furthermore, there must be sufficient power in the fingers themselves to make them of value along with the thumb. In a few individuals, particularly those in whom all the fingers flex in a mass as a result of tendon damage or a previous tendon transfer to the flexors of the fingers, the thumb is probably better utilized in adduction in which it can perform a pincers type of action against the radial aspect of the proximal phalanx of the index finger. It is, then important to emphasize again the necessity of accurately ascertaining whether the over all usefulness of the hand will be improved by the new action of the thumb.

Although the absolute prerequisites for the procedure have been enumerated there are other features which are desirable. It is, of course, advantageous to have relatively normal subcutaneous tissue for the rerouting of the transplanted tendons. This necessitates, in certain instances, the preliminary covering of the volar surface of the wrist and forearm with transplanted full-thickness skin by means of abdominal flaps or tubed pedicles. Occasionally the use of a pre-formed sheath, as has been suggested by Millgram and others, will tend to diminish the tendency for adherence of the transferred tendon to surrounding structures. We have employed this in only a few cases, and thus our experience is too limited to allow an appraisal of its value in opponens transplant. It is also desirable to have a strong action in the flexor pollicis longus tendon and reinforcement of this, if weak at the time of opponens transplant is usually of value.

CHOICE OF OPERATIVE PROCEDURES

There are two main types of operative procedures which have been employed in this group of cases. One is the Bunnell type of opponens transfer the second is the Thompson type. The Bunnell procedure (1) involves the use of a motor tendon rerouted on the proximal side of the transverse carpal ligament and so transferred and attached to the thumb that the line of pull on the thumb is directed toward the pisiform bone. A pulley in the region of

Fig. 1 Satisfactory substitution in an individual with complete paralysis of the opponens pollicis-abductor muscle complex. The thenar muscle mass seen is the flexor pollicis brevis, innervated by the undamaged ulnar nerve.

thumb with the exception of the method of tendon insertion. In our cases half of the sublimus tendon was inserted into a drill hole in the proximal end of the proximal phalanx of the thumb and the other half was inserted through a drill hole in the distal end of the metacarpal bone. These were fixed with the pull-out wire technique of Bunnell or on other occasions they were pulled through the drill holes and anastomosed one to the other in the subcutaneous tissues of the ulnar side of the thumb.

The application of fixation at the conclusion of the operative procedure is of utmost importance. As the dressings are applied the thumb must be worked into a position of opposition, abduction and particularly rotation with the use of numerous fluffed sponges and elastic bandage for accurate maintenance of this position. The metacarpophalangeal joint should be kept in a very slightly flexed position. A molded posterior plaster-of-paris splint is used to reinforce this dressing and straps are incorporated within it to provide a means of elevation of the hand for 72 to 96 hours postoperatively. When the entire dressing and splint have been applied the

Fig. 2 Completed tendon transfer in which the palmaris longus, rerouted around the flexor carpi ulnaris, is used and is prolonged with the extensor pollicis brevis.

thumb should be well out in abduction and rotation and the wrist should be flexed to about 45 degrees.

POSTOPERATIVE CARE

The dressing is first changed at 21 days at which time the pull-out wires are carefully withdrawn and the skin sutures are removed. The patient is then fitted with an adhesive and rubber band type of splint, fashioned so as to pull the proximal phalanx of the thumb toward the pisiform bone (Fig. 8a and b). He is then carefully instructed by the operating surgeon as to precisely what tendon has been transferred and how he may learn to use this tendon for opposition of the thumb. He is urged to practice diligently with this transferred tendon and for purposes of supervision in this he is referred to the Physical Therapy

across the metacarpophalangeal joint of the thumb. It will markedly flex this joint which is undesirable. In a few instances if the tendon is not dissected far enough distally, it will hyperextend this joint. Therefore, dissection must be carried out to just such a point that the desired rotation and opposition are obtained without either of the aforementioned undesirable actions. Occasionally also a slip connecting this tendon to the extensor pollicis longus must be severed so that it does not exert an extending action on the distal phalanx. In a few instances, despite severance of all connections to the long extensor tendon of the thumb, the extensor pollicis brevis continues to extend the distal phalanx. In such instances, it is probably best not to utilize this tendon but to use a free tendon graft for prolongation of the motor power.

In most instances in which a sublimis tendon, usually that of the ring finger, has been rerouted and directly inserted into bone, the end of the tendon has been inserted into the proximal aspect of the proximal phalanx of the thumb. This has been carried out by the drilling of a small hole from well on the dorsal aspect of the phalanx down through both cortices, in such a way that the tendon inserted into it from the dorsal to the volar side imparts not only abduction to the thumb but also rotation and opposition. The tendon is pulled down into the medullary cavity of the phalanx through the dorsal drill hole, and the pull-out wire technique of Bunnell is utilized to anchor it in place (Fig. 4).

A seemingly minor detail but one of great importance when the aforementioned method is used is the mobility of the metacarpophalangeal joint of the thumb. In a few cases this joint has been so mobile that it was impossible to insert the tendon into the proximal phalanx without the imparting of marked flexion at the metacarpophalangeal joint. In spite of a very proximal location of the drill hole. This possibility is explored by determination of whether or not traction on a suture passed through the drill hole in the phalanx exerts a satisfactory rotatory and opposing action on the thumb. If it does not, but instead causes marked flexion of the metacarpophalangeal joint, the tendon should not be inserted there but must be

inserted into the distal end of the metacarpal bone in a manner similar to that outlined in the phalanx. Despite any theoretic objections (1) to this site of insertion, the functional results have been excellent (Fig. 7).

In most procedures involving the Bunnell principle, some type of pulley must be utilized in the region of the pisiform bone. In instances in which the flexor carpi ulnaris is not utilized as a motor and in which it is functioning, the simplest and most satisfactory pulley is made by merely running the motor tendon over the flexor carpi ulnaris (Figs. 2 and 4). It is not advisable to mobilize the flexor carpi ulnaris, for this would allow it to bow somewhat radially. When the flexor carpi ulnaris is to be used as a motor or when it is non-functioning and thus would bow markedly to the radial side, the pulley can be constructed from part of this tendon as is shown in Figure 3. However we have found that insertion of the proximal end of the segment left attached to the pisiform bone into a drill hole in the very distal end of the ulna provided a larger pulley and thus one with less tendency toward adherence to the tendon passing through it. Furthermore, the pulley constructed in this fashion does not swing as much to the radial side as do others. A third method of construction of a pulley is to use a short free tendon graft as a loop, both ends of which are inserted into two drill holes approximately 1 centimeter apart, placed in the distal end of the ulna. This is particularly valuable when the flexor carpi ulnaris already has been used for transfer into the extensor tendons of the fingers or when it is contemplated that such a transfer will be carried out. In any instance, anastomoses of tendons should be placed well away from whatever type of pulley is used, the usually being accomplished with ease. It is obvious that the presence of such a pulley near a tendon juncture would increase the possibility of adherence at that point. When the extensor carpi ulnaris is employed as a motor, no pulley is necessary; the direction of pull of this tendon, after it has been rerouted, is toward the pisiform bone.

As noted earlier herein, we have on some occasions employed the Thompson procedure. We followed the technique originally described

Fig. 5 Skin incisions (In dotted lines) for transfer of palmaris longus muscle as shown in Figure 2. In addition to those incisions shown, a small transverse incision over the palmaris longus muscle is made in the middle third of the forearm through which this tendon is withdrawn and resected toward the pialform bone.

from the base of the first metacarpal bone through the same incision. These measures usually allow the thumb to be placed passively in the desired position. If sufficient release of the thumb still is not obtained in certain cases some further benefit may be obtained by capsulotomy of the carpometacarpal joint. The results of this procedure, however generally are less satisfactory than are those of severance of the adductor pollicis muscle.

Some residual paresis of the long flexors of the fingers occasionally occurs among these individuals. Most commonly the flexor digitorum profundus muscle to the index finger and the flexor pollicis longus are involved. If it is felt that this residual paresis is permanent reinforcement of the function that is already present is indicated. The flexor digitorum profundus of the index finger usually can be joined to the remaining profundus mass; this

Fig. 6 Skin incisions (In dotted lines) for transfer of flexor digitorum sublimis of ring finger with direct insertion into the proximal phalanx as illustrated in Figure 4.

should be done in such a position that with the long finger fully extended the index finger will be flexed to 45 degrees in all joints. Depending on the available tendons the flexor pollicis longus muscle can be reinforced with the palmaris longus or with one of the sublimis tendons. Although the procedure is not an integral part of the opponens transplant, it will increase the strength of the thumb in opposition.

RESULTS

There are a total of 84 cases in this series representing the results obtained by several different surgeons who used a variety of procedures. Information is available as to the methods employed in 75 cases. Of the 75 patients 67 were observed or traced for sufficient time to allow adequate evaluation. The results were classified as excellent, satisfactory, and unsatisfactory.

Excellent signifies the ability actively to abduct the thumb 2 inches (5 cm) from the

Fig. 3. Completed tendon transfer involving use of the flexor carpi ulnaris prolonged to the extensor pollicis brevis. Insert shows method of construction of pulley in such cases.

Department After a period of about 5 days gradual passive and active extension of the wrist is begun and after another 5 days the patient usually has begun to use the transfer in acceptable fashion. He is then allowed to discard the splint and to begin active use of the hand. The patient's movements are watched until it is assured that he is using the transplanted tendon well. A period of about 6 weeks after operation usually is required in order that the patient may become completely automatic in the use of the rerouted tendon for opposition.

In a few instances the patients have been slow in learning the use of the transferred tendons. In such instances it is wise to prolong the period in which the elastic splint is worn in order that the thumb may remain in a posi-

Fig. 4. Completed tendon transfer. The flexor digitorum sublimis of the ring finger is used, and is rerouted over the flexor carpi ulnaris and inserted into bone. Insert shows details of insertion of the tendon into the proximal phalanx of the thumb by means of pull-out wire.

tion of abduction, opposition and rotation, rather than fall back against the hand.

SUPPLEMENTARY PROCEDURES

In instances in which an adduction deformity of the thumb cannot be overcome by the previously described nonoperative means, the adductor contracture present generally can be corrected by division of the adductor pollicis muscle at its point of insertion. Exposure is procured by the making of a short longitudinal dorsal incision between the first and second metacarpal bones. Care should be taken to keep this incision as far proximal as possible, thereby precluding undue tension on the skin suture line when the thumb is placed in opposition and abduction postoperatively. If there seems to be any contracture of the first dorsal interosseous muscle it can be stripped

Fig 10. a and b, Excellent result obtained after a Bunnell type of transfer in which the flexor digitorum to the ring finger was utilized, with direct insertion into the proximal phalanx of the thumb in a patient with complete paralysis of all the intrinsic muscles of the hand

used as motor power was the only one available. Therefore the incidence of the methods does not accurately reflect the choice of procedures in cases in which the injuries were uncomplicated

The question naturally arises as to the deficits resulting from transfer of the motor tendon. The rerouting of the palmaris longus muscle, of course, results in no loss of function. Similarly there is essentially no disability when the flexor carpi ulnaris or extensor carpi ulnaris is used. The function of a flexor digitorum sublimis when it is transferred is taken over by the flexor digitorum profundus in question to such an extent that its absence cannot be determined by clinical examination. In no instance has any patient felt that his finger was noticeably weakened by transfer of a flexor digitorum sublimis

ANALYSIS OF FAILURES

In this series there were as previously pointed out 12 cases in which the result was classified as unsatisfactory. An analysis of these cases is enlightening as to pitfalls to be avoided

In 2 instances the thumb was in good position 3 weeks postoperatively but returned to an adducted position during the ensuing 2 to 3 weeks and never showed active opposition. In both of these cases the operative sites were re explored. In the first instance the anastomosis between the palmaris longus and extensor pollicis brevis was found to have disrupted

The flexor digitorum sublimis to the fourth finger was then utilized as a motor it was inserted into the proximal phalanx of the thumb with an excellent result. In the second instance the short extensor had apparently disrupted from its insertion over the proximal phalanx probably because of excessive dissection. The flexor digitorum sublimis to the third finger (that to the fourth having been utilized in the previous procedure) was then used it was inserted into a drill hole with resulting excellent function. From the experience reflected in these 2 cases it should be concluded that re-exploration is indicated in cases in which the function of opposition and abduction is not manifested postoperatively

palm oppose it to the tip of the ring finger and to rotate it so that the plane of the nail is within 20 degrees of the plane of the palm. These are essentially those movements possible in a normally functioning hand. If the thumb was deficient in the slightest degree in any of the above criteria, the result was *not* considered excellent but only satisfactory.

In all cases in which movement of the thumb was rated satisfactory there was a decided

improvement in function and the patient was satisfied with his result.

In those cases in which there was no appreciable improvement over the preoperative condition function was rated 'unsatisfactory.'

In Figure 9 is illustrated the typical preoperative function in all the hands concerned in the present study.

Among the 67 cases in which function was evaluated it was classified as excellent in 7 (Figs. 10 and 11) and as satisfactory in 13 (Figs. 12 and 13). In 12 cases the result was judged to be failure. The data are summarized in Table I.

It is seen from examination of the data that every method is capable of giving a good result. In general the degree of success was directly proportional to the completeness of fulfillment of the prerequisites for transplant without regard for the method employed. As an example, in hands with fixed deformities of sufficient severity to necessitate severance of the adductor pollicis muscle, there were no excellent results. However, although the results in these cases were given only a satisfactory rating, the functional result considering the over-all condition of the hand actually was an excellent one in each case, and it was felt that maximal improvement had been obtained.

The variety of methods utilized in this series resulted from the fact that many of the injuries were of such nature that the muscle

*Except for the group entitled "Thompson method," the Bunnell type of procedure as employed and the designated tendon used as motor source.

†If additional cases no information was available as to the details of the procedure employed or the results obtained.

In 3 instances of failure the opponens transplant was but one part of a multiple-tendon transfer procedure. This resulted in compromise in the securing of correct tension and ideal position with ultimate failure. When other tendon transplant operations about the wrist are performed the opponens procedure usually will profit by being postponed to a later date. This in addition simplifies the problem of re-education for the patient.

In 2 cases the tension on the completed anastomosis was extremely slight, which may well explain the failure which occurred. Fixed deformities of parts of the hand other than the thumb were present in 2 cases, and were of such severity that they could not be overcome.

Operation for these individuals was ill-advised, and the resulting failure could be anticipated. In another instance because of an unfortunate oversight the motor utilized was a paralyzed muscle. In 2 cases the causes of failure were undetermined because the patients had been dismissed from the hospital and thus were not available for evaluation.

This analysis of the failures serves well to emphasize the prerequisites, since in many of the aforementioned instances they were not present and failure followed. We feel that in future cases there should be no instances of failure.

COMMENT AND CONCLUSIONS

A series of cases has been presented in which a variety of types of opponens transplant was carried out. The indications and prerequisites for this procedure have been discussed, and the technical details of importance have been related. An analysis of the series has been presented in an attempt to judge the end results. The failures have been discussed with a view to prevention of such poor results in future cases.

The over all study of this group of cases allows the formation of some conclusions as to the methods of choice to be employed. In the usual case it is probably preferable to use the Bunnell type of operation since the Thompson procedure, although satisfactory fails to give quite as much abduction as does the former type. In cases in which there is marked scarring about the volar surface of the wrist, the Thompson procedure is preferable in order that the operation may be carried out in normal tissue.

When the Bunnell method is employed it is probable that a good result can be obtained from the use of any source of motor power. In instances in which all possible sources of motor power are available in good strength, including a rather strong palmaris longus muscle, and cases in which the extensor pollicis brevis on surgical exploration is found to be sturdy and to give the desired action on the thumb, the use of these in the manner described (Fig. 2) is very satisfactory. If the palmaris longus is thin or weak however or if the short extensor of the thumb is attenuated or exerts a poor

action on the thumb it is probably wise not to employ this method but to use instead the flexor digitorum sublimis tendon to the ring finger severed within the digital sheath with direct insertion of it into the thumb in the manner described (Fig. 4). Furthermore, if there is some adduction deformity of the thumb and a strong motor source is desired such use of the flexor digitorum sublimis to the fourth finger is of even greater advantage.

In point of fact the use of this method has certain definite advantages over all others. It provides very strong motor power with excellent excursion. There is no anastomotic site to become adherent to surrounding structures. The insertion of the tendon into bone is so durable as to render disruption virtually

impossible. At present it would be our method of choice.

If these tendons are not available however a good result can be procured by carrying out an accurate procedure in which any of the methods discussed are employed. The important considerations are attention to the prerequisites for a good result and care as to the technical details of the operative procedure.

TREATMENT OF PERSISTENT COLON BACILLUS INFECTIONS OF THE URINARY TRACT BY SULFASUXIDINE AND STREPTOMYCIN

EDMUND CROWLEY B.S., M.D. F.A.C.S. and VINCENT J. O'CONNOR B.S., M.D. F.A.C.S.
Chicago, Illinois

MODERN drug and antibiotic therapy has enabled us to eradicate a large percentage of the non surgical infections of the urinary tract in a manner which would have seemed almost miraculous a decade ago. There are however a number of patients both male and female who respond favorably to treatment for a short time but who suffer recurrence of infection shortly after therapy is discontinued. Still other patients do not achieve permanent urine sterilization by any previously employed combination of medical or instrumental treatment.

It is well to initiate this discussion by emphasizing the fact that the efficiency of modern urinary antiseptics should in no way moderate the absolute necessity for a thorough urological examination in each patient suffering from a urinary tract infection. The search for as well as the eradication of any extraordinary focus of infection remains as important today as it was heretofore. The correction of any lesion which causes obstruction to the free outflow of urine is of paramount importance before medical management can be permanently successful.

Our experience parallels that of most other observers in that we have found a predominance of the colon typhoid or coliform group of organisms as the main cause of urinary tract infection. In most individuals in whom there is no associated obstructive uropathy the urinary infection can be eradicated by the removal of systemic foci of infection and the administration of the proper urinary antiseptics. The ingestion of mandelic acid or sulfa

derivatives, or the alternate use of these drugs has been effective in a large percentage of our patients when the colon bacillus has been the principal infecting agent. Where coccal organisms are also present in the urine, penicillin is indicated in conjunction with sulfa or mandelic acid compounds. At times the older urinary antiseptics such as hexamethylenamine in its various forms, may prove effective in sterilizing the urine when our modern drugs have failed.

Herrold has recently suggested methods for *in vitro* tests of susceptibility to penicillin and streptomycin of the bacteria found in non-specific infections of the urinary tract. Tests of susceptibility by using exudates or smears enable a prompt grading and in addition, where mixed infections occur the relative susceptibility of the various organisms can be determined.

Wider clinical application of these principles may enable us to determine more quickly which medication is most applicable for the patient at hand. Despite our increased success in the treatment of colon bacillus infections of the urinary tract with the newer antiseptics and antibiotics, we continue to encounter individuals in whom we have eliminated all extraordinary foci and in whom we have repeatedly demonstrated that there is no obstructive uropathy but where we have been unable to clear the urine permanently of the infecting organisms by varied medication.

The question naturally arises: Why do these individuals continue to have recurrences? Is it because they are infected with an unusually virulent strain of bacteria or do they continue to have a systemic focus of infection which reinflects the urinary tract?

Kauffman of Copenhagen has shown that certain strains of colon bacilli are recognized

From Urological Department, Wesley Memorial Hospital and Northwestern University Medical School, Chicago, Illinois.
Dr. Crowley was formerly Miles Laboratory Fellow in Surgery at Wesley Memorial Hospital and Northwestern University Medical School.

important etiological agents in infections of the urinary and bile tracts and particularly in producing appendicitis. While we have all agreed that the transfer of organisms from the large bowel to the urinary tract can and does frequently occur, clinical proof of this is often difficult or impossible. Our interest in further attempting to limit the colon bacillus content of the large bowel by sulfasuxidine was stimulated by the report of Everett Scott and Steptoe who described the successful use of this drug in the treatment of acute pyelitis of pregnancy due to the colon bacillus in pure or mixed culture.

Our recent associate, Dr. Robert McAllister, began the treatment of a group of patients with resistant urinary tract infections by giving sulfathaladine and later sulfasuxidine as the sole medication. From 8 to 10 grams of the drug were given daily for the first 2 weeks and then 4 to 5 grams daily for an indeterminate period of from 8 weeks to 10 months. In general this selected group of patients responded favorably to this treatment. The urinary symptoms were reduced, constipation was often completely relieved and the pyuria was diminished. These patients experienced enough improvement to be willing to continue the therapy. Despite the prolonged ingestion of sulfasuxidine they were remarkably free of toxic symptoms. One woman complained of dizziness and anorexia and these symptoms subsided promptly with discontinuance of the drug. Patients may be sensitive to sulfasuxidine but Bergen found the toxic reactions of sufficient severity to indicate discontinuance of the drug in only 1 per cent of 2000 patients. Roth reported an occasional skin eruption or febrile reaction in patients sensitive to sulfathiazole. Hematuria and crystalluria in one patient were reported by Clay and Pickrell. In 1943 Johnson reported a fatal instance of agranulocytosis apparently due to sulfasuxidine. None of these complications developed in our patients. Despite the clinical improvement sustained during this therapy the colon bacilli persisted in the urine or recurred shortly after discontinuing treatment.

Sulfasuxidine is the trade name for succinylsulfathiazole. About 5 per cent of the drug is said to be excreted in the urine as sulfathia-

zole. Roth and his associates reported a blood level of free sulfathiazole rarely above 15 milligrams per cent in patients taking 25 gram per kilogram weight in six divided doses every 24 hours. Extensive studies have proved that both sulfasuxidine and sulfathiazole are sparingly absorbed from the bowel and have their action limited largely to the gastrointestinal tract. Roth has stated the amount of drug required to alter the intestinal flora will be determined by the content of the bowel, its mucosal surface area and the rate at which the drug passes over the surface rather than by the weight of the patient. The coliform bacilli in the feces is reduced to less than 1000 organisms per gram of wet stool when 30 grams of sulfasuxidine is given by mouth every 4 hours to adults in the following times: (1) 37 per cent in 3 days of therapy, (2) 80 per cent within 5 days and (3) 94 per cent within seven days. The stools become semifluid, smaller in bulk, relatively odorless and there may be three to four movements a day. A voluminous literature with many detailed case reports verify the value of this drug in the preparation of the bowel for extensive surgical procedures.

During the course of the above study a few grams of streptomycin became available to us for experimental purposes. Because of the extreme resistance of a colon bacillus infection in the only remaining kidney of a man 60 years of age who had previously received all manner of modern treatment and who had been on sulfasuxidine with slight improvement for 3 months a total of 5 grams of streptomycin were administered to him over a period of 6 days. The urine rapidly cleared to complete in 3 days with negative cultures after the fifth day. This patient was continued on 4 grams of sulfasuxidine daily for 4 months after leaving the hospital. It is now 16 months since the urine has shown pus or bacteria. The apparent complete cure of this most resistant infection by combined sulfasuxidine and streptomycin administration has prompted us to use this combination in a series of 23 patients. All of these patients had been under observation for from 3 months to 20 years without an effective or lasting eradication of the colon bacillus from the urine. The results obtained

have been so uniformly successful, and so much more noteworthy than when streptomycin alone was employed that we feel this combination offers the possibility of an effective method of cure in a greater percentage of these resistant cases than has been obtained by other methods of medication heretofore employed.

In attempting to explain the reason for urine sterilization in these patients, in whom all previous methods had failed the question naturally arises as to whether or not this combined medication has succeeded because it has lessened the colon bacillus transfer from the bowel to the urinary tract and thus permitted the natural immunity of the individual to complete the eradication of the infection.

Reports, which are daily becoming more frequent of the results one may expect to obtain by the administration of streptomycin for colon bacillus infection of the urinary tract suggest a favorable response in 45 per cent to 60 per cent. The committee on chemotherapeutics (Keefer and associates) reported a 52 per cent recovery in 154 patients with *Escherichia coli* infection of the urine 25 per cent improved and 21 per cent not affected. Of the patients that improved 19 per cent relapsed after treatment was stopped. Nearly all the relapses occurred in one week. Findlay reported the failure of streptomycin in 5 of 6 cases of *Bacillus coli* infection of the urinary tract. He explained the failure as being due to the rapid development of extreme resistance to the antibiotic.

The favorable response in our patients has been approximately 85 per cent. That the streptomycin alone has not been the conclusive factor seems demonstrated by the fact that those of our patients who could not tolerate the continued ingestion of sulfasuxidine had a relapse of urinary infection. This relapse occurred in 2 of our patients.

CASE REPORTS

Mrs. J. K. age 60 years, gave a history of intermittent attacks of chills, fever and pyuria for a period of 35 years. Urine cultures showed a heavy growth of *Escherichia coli*. The pyelographic studies were negative for obstructive uropathy. All types of urinary antiseptics had been administered. On a few occasions the urine cleared of pus but negative cul-

tures were never reported. On May 20, 1946, patient entered Wesley Memorial Hospital. Ten million units of streptomycin were administered. Cultures of the urine were reported as negative May 26. Two days before leaving the hospital the patient developed an intolerance for the sulfasuxidine and refused to take further dosage of the drug. Subsequent cultures taken at the office were reported as follows: June 12, 1946, negative after 48 hours; July 23, 1946, negative after 48 hours; August 2, 1946, negative after 48 hours; December 14, 1946, *Bacillus coli*; January 13, 1947, *Bacillus coli*; May 15, 1947, *Bacillus coli*.

Mrs. O. W. age 48 years, gave a history of "chronic cystitis." All manner of urinary antiseptics had been tried but cultures were always positive for colon bacilli. This patient entered Wesley Memorial Hospital on May 23, 1946. The urine showed *Escherichia coli* 5 million units of streptomycin was administered. Cultures of the urine were reported on June 3 and 8. The sulfasuxidine had to be discontinued because her referring doctor was not interfered with the patient's ulcer management and aggravated the ulcer pain. Subsequent cultures from the office were reported as follows: July 4, 1946, *Bacillus coli*; August 26, 1946, negative; October 4, 1946, negative; November 6, 1946, *Bacillus coli*; November 18, 1946, *Bacillus coli*; May 14, 1947, *Bacillus coli*.

We were unable to obtain negative cultures at any time in 2 of our 23 patients.

Mrs. L. W. age 65 years, gave a history of a right nephrectomy in 1932 for a calculeous prostatic. In December 1944, a left nephrostomy with pyeloplasty was performed for a pyohydronephrosis. There was good visualization of kidney and emptying of the pelvis and bladder. Sulfasuxidine (4 grams daily) was administered for 8 months before the first 5 million units of streptomycin were given. The urine became clear but remained positive for *Escherichia coli*. A second course of streptomycin (10 million units) was prescribed but the cultures remained positive. Following the streptomycin the patient developed dizziness and inco-ordination. Nine months have passed since the streptomycin was given. The dizziness had completely disappeared. A culture on May 17, 1947 was positive for *Bacillus coli*. Urine showed 10 to 20 pus cells per high-power field.

The second case that failed to show negative cultures at any time on combined sulfasuxidine and streptomycin therapy was that of Mrs. H. G. age 34 years.

Retrograde and intravenous pyelograms showed a hypoplasia of the right kidney. We believe the function of this kidney was too poor to concentrate the streptomycin in sufficient quantity to inhibit bacterial growth. A nephrectomy is probably indicated.

TABLE I.—SUMMARY OF 23 CASES

T. U. R. transurethral resection.

To the present time 19 of our 23 patients have sterile urine. In none of these cases was more than 5 grams of streptomycin administered. Sulfasuxidine was given before, during and following the administration of the antibiotic.

The following brief case histories illustrate the type of patient so treated.

R J, age 58 years, white male gave a history of pyuria of 15 years duration. In 1943 a left nephrolithotomy was performed. Urine cultures have been persistently positive for *Bacillus coli* in spite of the liberal administration of penicillin, sulfonamides, mandelic acid, urotropin and mandelamine. Retrograde pyelograms showed a left middle hydrocalyx. A negative urine culture was obtained after 3 million units of streptomycin had been given. A total of 5 million units were administered. Urine cultures have been taken at 2 to 4 week intervals and all have been negative for growth. The patient left the hospital on May 24, 1946. He continued to take 4 grams of sulfasuxidine daily without toxic effects for 5 months. April 18, 1947 urine cultures were negative.

B S, age 50 years. This patient had two transurethral resections of the vesical neck in 1943 and a third in 1945. Intravenous pyelograms showed normal outlines. Urine cultures were positive for *Bacillus coli*. After a preliminary course of sulfasuxidine this patient entered Wesley on September 16, 1946 for a course of 5 grams of streptomycin. Urine cultures were sterile on the 18th and 20th. All subsequent cultures have been negative. About 3 months ago the patient discontinued the sulfasuxidine of his own volition because he thought it was becoming toxic to him. The last culture on May 15, 1947 was negative. The urine is clear, free of pus and the patient is well in every respect.

F G., age 66 years. This patient, like the one just reported, had had three transurethral prostatic resections the first in 1941, second in 1944, and third in 1945. Symptoms of nocturia, frequency and burning persisted because of a chronic cystitis due to *Bacillus coli* infection. The severity of the symptoms was modified by the use of sulfasuxidine. On October 18, 1946 the patient entered Wesley Memorial Hospital. A negative urine culture was obtained after the administration of 4 grams of streptomycin. The urine is negative to the present time. The patient has taken 3 grams of sulfasuxidine daily for 7 months.

P H., age 56 years. Five years ago a papillary carcinoma of the bladder was coagulated transurethrally. In February of 1943 the left ureter was transplanted into the bladder because of a stricture of the orifice. The urine has been cloudy with pus. Urine cultures showed a heavy growth of *Aerobacter aerogenes*. On November 21, 1946 the patient entered Wesley Memorial Hospital. A cystoscopic study showed a slight enlargement of the median and left lateral lobes of the prostate. A retrograde pyelo-

ureterogram showed a grade II left hydronephrosis. Five million units of streptomycin were given. Urine cultures were reported as negative on November 21. The pus count was 2 to 4 cells per high-power field as compared with numerous cells on admission. Subsequent cultures have been negative. The patient continued to take 4 grams of sulfasuxidine daily for 6 months. Cultures on June 10, 1947 were negative.

Fifteen female and 8 male patients varying in age from 73 to 23 years have been studied in detail. Each of these patients had an unusually resistant urinary infection, 22 with positive urine cultures for *Escherichia coli* and one with *Aerobacter aerogenes*. Obstructive lesions in the urinary tract were ruled out in each patient by complete investigation. The duration of recurrent urinary infection ranged from 33 years to 1 year. The average time for the entire group was 8 years. Ten of these 23 patients had had surgical operations upon the urinary tract.

It is now 17 months since the first patient was placed upon the combined therapy of sulfasuxidine and streptomycin (Case 1). His urine has remained negative to culture and free of pus for this time. Prior to this treatment his urine had been constantly infected for a period of 5 years. Two patients have had sterile urine for 14 months, 2 for 12 months, 2 for 9 months, 6 for 8 months, 1 for 7 months, 4 for 6 months and 2 for 4 months.

CONCLUSION

We are of the opinion that this series of patients, although small in number, suggests an unusual efficacy in the combined administration of sulfasuxidine and streptomycin in otherwise resistant bacillary infections of the urinary tract.

Of 23 patients so treated 19 have maintained a completely favorable response for periods sufficiently prolonged to suggest the probability of permanent cure. As previously described in detail these patients received sulfasuxidine for varying periods before, during and after the administration of 5 to 17 grams of streptomycin.

Sulfasuxidine or streptomycin given alone has not had the favorable effect observed in the combined therapy. Success in the 19 patients with long standing resistant infection

seemed dependent upon the patients ability to continue the ingestion of sulfasuxidine. Fortunately the toxicity of sulfasuxidine is low and the drug can be given in large doses for long periods of time.

Toxic symptoms if they occur subside rapidly when the drug is discontinued.

This study is reported in detail in the hope that it will encourage a more widespread trial of this, or some similar combined therapy in

the treatment of otherwise resistant urinary infections of bacillary origin.

THE RADICAL TREATMENT OF BRAIN ABSCESS

JERZY CHOROSKI M.D. and ADAM KUNICKI M.D. Warsaw Poland

BRAIN abscess is generally considered to be one of the most serious pathological conditions of the central nervous system the treatment of which is difficult and the prognosis doubtful. It seems however that such a pessimistic view is unfounded and its existence best explained by the consequences of the mistakes physicians often commit in not distinguishing between the two different stages of one and the same disease e.g. between the purulent encephalitis and the abscess proper. Consequently operative treatment which is indicated for an abscess, is applied when the suppurative process has still not been localized, that is when there is no indication for surgical intervention. It is difficult indeed to treat an abscess before it has formed.

Success in the treatment of cerebral abscess depends principally upon the moment surgical intervention is applied. The excellent and up to now unparalleled results obtained by MacEwen who from his 19 patients suffering from cerebral and cerebellar abscesses lost only 1 were chiefly due to the fact that he never used drainage in an acute stage of the disease but waited for proper encapsulation of the abscess.¹ He was no doubt, entitled to say that an uncomplicated brain abscess may be regarded as the most hopeful of all cerebral affections.

According to Adson and Craig it took us many years to learn that hasty emergency operations were futile and were accompanied by high mortality. This, undoubtedly was due to the insistence of colleagues that we do something as soon as a diagnosis of cerebral abscess has been made.

From the Neurosurgical Service of the Neurological Clinic, University of Warsaw.

According to F. y. Ambroise Paré reported in 1668 series of cases of abscess of the brain with remarkably low operative mortality. This was mainly due to the fact that he waited for localization and encapsulation of the abscess before operating. He first trepanned the skull over the lesion and 3 days later incised the dura mater allowing the brain to bulge forth. For drainage he used lead cannulas.

We must then define the term abscess, in order to find a reason for the somewhat unsuccessful results obtained in the treatment of cerebral abscesses. Experience shows that these are due not so much to mistakes in diagnosis or localization of the lesion as to the improper time chosen for operation. "No experienced surgeon would consider incising and draining an abscess in any other area of the body before encapsulation was completed" (18). Why then do so many surgeons behave differently in a case of cerebral abscess?

An abscess is, according to Lecture "a collection of pus in a new formed cavity distinctly limited from the surrounding tissue and which represents the end-result of an acute inflammatory process." The accent lies here on the statement that the abscess is the "end-result of an acute inflammatory process and that it is distinctly separated from the surrounding tissue."

"The reaction of the brain to focal purulent infection resembles the reaction of the other organs of the body to such a process in that there is rapidly formed a mesoblastic barrier about the bacterial focus. That is, of course, assuming the infection can be limited at all" (41). An abscess is the result of a protective process which is advantageous to the body and testifies to its resistance to the pathogenic organisms. If on the other hand, the virulence of the organisms is too great or the resistance of the body too weak no abscess will develop and the local inflammation of the brain will change into an encephalitis spreading over one or even both cerebral hemispheres.

The first fibroblasts, that is, the first signs of a capsule, appear around the liquefying focus of inflammation at the end of the first week, the capsule becoming mature and offering firm elastic resistance to the exploring brain needle only at the end of the second or even the third week (17, 21, 41). The development of a firm capsule requires a somewhat longer time in the case of an abscess of the

brain than in similar lesions located elsewhere in the body, probably because the brain contains less connective tissue and it is connective tissue which is the decisive element in any encapsulation. Actually Huguenin missed the capsule in an abscess of 32 days' duration and in another of 53 days' duration the capsule was still very thin. He found a thick elastic capsule only in a case of a brain abscess which had lasted for 83 days. Bergmann (6) states that Meyer examined the formation of the capsule in 21 cases of posttraumatic cerebral abscesses and came to the conclusion that the first signs of encapsulation appear 19, 20 and 25 days after the infection; the capsule becoming firm only in the sixth week of the disease. According to McKenzie a cerebral abscess is well encapsulated 4 to 5 weeks after the infection. Grant found that in the first 2 weeks of the disease only 3 out of 13 abscesses were encapsulated; between the third and fourth week 10 out of 18 already had a well developed capsule, and after 6 weeks all abscesses were definitely and distinctly walled off. Groff asserts that the resistance of the capsule to the exploring needle is well marked at the end of the third week after infection and Kahn states that he observed a patient in whom an abscess of 10 days' duration was already well encapsulated.

It is obvious therefore that the time necessary for the development of a capsule varies in each case, this fact being most probably due to a number of circumstances such as individual differences in the virulence of the organisms, method of invasion, degree of resistance of the body, etc.

However, it may be that one should not expect a cerebral abscess to be well encapsulated before the end of the third week after the infection and that before that time there is little hope for surgical intervention to end successfully. According to Grant who studied in detail the relationship between the success of the treatment and the duration of the disease the mortality in 30 cases of encapsulated abscesses was 33.3 per cent, while in the 19 cases of unencapsulated abscesses it reached 100 per cent. The best operative results were obtained when the patients were treated 4 to 6 weeks after the infection. If a patient dies

before the abscess is properly encapsulated that is before the proper time for operation is reached, the reason lies not in the postponement of surgical intervention, which at that time could only have been harmful but in the absence of sufficient resistance of the body to the infection. The rupture of a well encapsulated abscess rarely occurs more often the patients die because of an operation performed too early than because of surgical intervention applied too late. Out of 49 patients of Grant only 2 died because operation was delayed too long but 14 died because it was performed too soon.

There is now indeed no divergence of opinion as to the fact that operation for a cerebral abscess before capsule formation has taken place is nearly always fatal, yet the choice of the preferable procedure is still a much debated question. The treatment indicated is always surgical because although there are undoubtedly cases of brain abscess which come to self healing such an occurrence is very rare and the disease not properly treated ends sooner or later in death of the patient.

Without entering here any details of the history of the surgical procedures which have been and are still carried out in the treatment of cerebral abscess it is sufficient to say that the following are the most frequently used: (1) single or repeated tapplings of the abscess with emptying of its contents and with or without the introduction of penicillin into the abscess cavity; (2) drainage of the abscess; (3) extirpation of the abscess either intact or after evacuation of its contents. This last method of treatment seems to us to be the most rational but it has up to now been used by the majority of surgeons rather reluctantly. It is difficult to perceive the advantage of tapping or draining an encapsulated abscess over its removal *in toto*. On the contrary, it seems that there are many reasons why the last procedure should be the method of choice. It is as safe for the patient as the others and when crowned with success cures the patient more quickly and finally. Indeed it is difficult to understand why the removal of the overlying cortex and the upper dome of the capsule with consequent fungus formation as practiced by King (24) Kahn and others, should be safer

and less damaging than the removal of the abscess intact. Undoubtedly it is possible that a latent inflammatory process may sometimes persist around an abscess and be reactivated even by the most careful handling of the brain tissue. Such a complication however may follow any other surgical procedure as well. In fact this is a frequent consequence of drainage so much so that Coleman (10) is of the opinion that this phase of the treatment is still unsatisfactory and that there are inherent risks attending drainage of any kind. Usually, the brain resists such a reactivation of the inflammatory process, having already demonstrated its powers of resistance in limiting and encapsulating the primary focus.

It is certainly true that penicillin introduced into the abscess cavity through a small burr hole—a very simple procedure, may sometimes sterilize the abscess and consequently cause the capsule to shrink. Yet to leave the capsule *in situ* is equal to leaving in the brain a connective tissue scar which contracting must finally cause epilepsy. There is surprisingly little known about this complication of cured cerebral abscesses although one would *a priori* expect epileptic seizures to be a rather frequent sequel of nonradically treated abscesses. Dandy (12) the originator of the method of aspiration of brain abscesses states that in a few of his patients thus treated epilepsy developed 2 or 3 years later necessitating the resection of the part or the whole of a cerebral lobe containing the scar of the old abscess. Adson and Craig complain that epilepsy develops too often following abscess and that is why they are gradually becoming convinced that secondary operations, scar resections, as practiced by Penfield are indicated in selected cases a year or later following the initial operation. Penfield and Erickson (42) noted that 8 patients out of a group of 33 who recovered from cerebral abscess have had seizures after operation. In other words 24 per cent of their patients developed epileptic seizures due to the cicatrix left by the drainage or evacuation of a brain abscess. The patients were all traced for only 1 year or more and the authors presume that a longer period of follow up would undoubtedly result in a larger percentage.

Last but not least, recovery after the radical removal of a brain abscess comes on faster than after its drainage. In the first instance the convalescence lasts weeks, in the second sometimes several months. Finally it may be emphasized—and this is the result not only of our own observations but also of those of many others—that the evacuation of a brain abscess although it is large and situated deep in the white matter damages the brain surprisingly little. In all events, it is by no means more harmful than removal of a large meningioma or other benign brain tumor. The signs and symptoms which are sometimes many, accompanying brain abscess usually subside completely showing that often the clinical picture is produced chiefly by concomitant brain edema, toxicity of the pus, etc. However, the radical treatment although theoretically commended by many was up to now applied only by a few.

Busch advocated the removal of the capsule but only after its incision and the evacuation of the pus, adding that in certain circumstances this procedure is rather simple. Ballance is of the opinion that the treatment of encapsulated cerebral abscesses should consist of their radical removal. He cites however no observations in which this postulate has been realized. Bergmann (6) notes that if during the drainage of an abscess "its membranous wall is forced into the brain incision it should be seized and removed. However it was Kronlein who first removed a brain abscess *in toto*. He performed this operation on a woman aged 38 years, who developed Jacksonian epilepsy 5 years after a skull injury. At the operation a subcortical abscess, the size of an egg was found in the left frontal region. The author stresses the fact that such a radical removal of an abscess, which incidentally was diagnosed as brain tumor presents "a rarity in the literature concerning the subject. Krause states that chronic abscesses should be evacuated and the capsule removed, and Rawling states that since the drainage of an abscess seldom permits a permanent cure, the abscess filling up again as soon as the tube is withdrawn "it is generally advisable to attempt the entire removal of the abscess wall. As a rule there is no great difficulty attendant

in this process and the haemorrhage is seldom severe. According to Oppenheim (40) Bil

eter removed a brain abscess *in toto*. Bagley

discussing his 21 cases of cerebral abscess

mentions one in which the lesion was diagnosed as brain tumor and removed radically.

The patient recovered yet the author considers that we should not be led to practice this method which entails the removal of the protective membrane and exposes the brain to

any organisms and may result in a diffuse encephalitis. Sargent has had 5 cases of total

removal of posttraumatic cerebral abscess diagnosed properly before the operation. Bal

lado and Franke, although they are of the opinion that the best treatment of brain abscess

is its total removal assert that this ideal is only rarely realized. They say that the capsule of an abscess consists of not one but of

several layers which do not represent the true limits of the inflammatory process. Coleman

(12) writes that although in rare cases an abscess was successfully removed with its capsule

of rupture during removal appear too great to allow this to be a premeditated method of

dealing with brain abscess. The attitude of the author toward the radical removal of cerebral abscesses is therefore, negative in spite

of the fact that, as he states, a recurrence is a possibility in all methods except

perhaps where the entire capsule is removed. In 1946 he apparently changed his opinion as

he states that 'there is a good deal to be said for the radical extirpation with the capsule

in multiple abscesses or in those in which a large granulomatous mass forms which cannot

be eradicated. Adson and Craig consider that 'when it is possible to remove the abscess

and capsule without opening it this hastens recovery'. Adson in fact removed a brain

abscess without being aware that he had done so until the mass was opened after operation.

The wound healed by primary intention and the patient recovered fully. They say how

ever that our experience with removal of capsule following evacuation of the pus has

not been satisfactory since a secondary suppurative encephalitis develops that is more

troublesome to treat than the original infection.

The publication of Clovis Vincent in 1936 was an important milestone on the road leading to the more frequent use of the radical

treatment of cerebral abscess (51). His method of dealing with those lesions is as follows. If

there is a necessity for surgical intervention in an early stage (only however after 3 weeks

since the beginning of infection) on account of the severity of the patient's condition while

the abscess is not sufficiently encapsulated to be dealt with radically it should be localized

precisely by means of ventriculography and then the brain decompressed by a large osteo-

plastic flap turned down over the site of the lesion. After the aspiration of the pus the

bone flap is replaced without the dura being opened. The aspiration may be repeated

Once the abscess is firmly walled off it is dissected out intact. Applying this method in

3 cases of so-called subacute brain abscess Vincent obtained complete recovery in all of

them. In 2 other cases the abscess was removed *in toto* during the first operation with

out the brain being decompressed and the abscess aspirated. His assistants Puech, Tho-

mas and Brun (45) and Puech, Mahondeau and Askenazy (44) published their own ob-

servations of cases in which the abscess was also removed intact. In the second of those

2 cases the abscess was extirpated from the cerebellum a unique experience up to that

time. Vincent and his coworkers have had therefore 6 recoveries in 7 consecutive brain

abscesses. In all 7 patients the lesion was diagnosed properly before the operation and

the method of treatment applied with premeditation.

Cairns points out that in some chronic abscesses the capsule is so thick that the abscess

must be removed intact like a tumor. In others the abscess is loculated to such an extent that

thorough drainage is impossible and excision is the only treatment. In yet others there are

two or three separate though continuous chronic abscesses.

Lehman mentions only that radical removal of the brain abscess is feasible only in cases of old abscesses with a

strong capsule and thick contents. Yaskin Grant and Groff (56) at a meeting of the Neurological Society in Philadelphia presented 2 cases in which the abscess diagnosed

as brain tumor was successfully removed. In the discussion Grant said that he found it feasible to give the abscess a chance to form and coalesce and then to shell out the whole mass. He thinks that if the abscess is encapsulated one can do almost anything with it. Dandy's (13) ideas on the subject are different. He states dogmatically that one would suppose that because the abscesses undergo a firm encapsulation they are suitable for enucleation with a finger like some of the brain tumors. Attempts to do so are almost always harmful. The infection which is present in the capsule is still active and it can be easily awakened. A diffuse encephalitis and a wound infection is then unavoidable. I have seen only once an abscess successfully removed. Stich and Bauer believe that only seldom there is any need for removal of an abscess as in the majority of cases repeated aspirations are sufficient. Odom and Elvidge relate a very interesting experience of complete extracapsular removal of two abscesses resulting from infection of the brain by the *Bacillus typhosus*. Northfield strongly advocates enucleation as the proper method in dealing with brain abscesses. In his experience only 1 patient died out of 8 in whom enucleation was carried out. According to him the criteria to guide one as to when to enucleate the abscess are as follows: the subsidence of acute inflammation and the formation of a tough wall. However if the operation is unduly postponed it becomes technically more difficult owing to the formation of an excessive degree of scarring around the abscess leading to an unnecessarily wide excision of tissue. Secondary loculi or separate deeply placed abscesses may develop if a case is left too long. The third month i.e. between 8 and 12 weeks appears to be the time of election for enucleation. Nowicki extirpated radically 8 abscesses of the brain. In 6 cases he obtained good results. In one instance the patient died after the operation from meningitis and in another the patient was taken home soon after the operation in a serious condition and nothing is known about his later fate. Ferens mentions that he removed a brain abscess successfully. Pennybacker reviews the experiences of the Nuffield Depart-

ment of Surgery in Oxford, and analyzes the results of 50 consecutive cases of cerebral abscess. Whereas in the 21 cases in which simple aspiration, tube drainage, open drainage (Finckh method) and aspiration plus decompression were performed there were 13 fatalities, of the 26 cases in which the abscess was excised only 2 patients died. Primary extirpation was carried out in 7 cases, extirpation after aspirations in 11, extirpation after aspirations and decompression in 8 cases. One patient who died had multiple bronchogenic abscesses in both hemispheres and the other developed a fatal meningitis after primary extirpation of an abscess due to mastoid infection. In conclusion Pennybacker states that "we think this method is applicable in most cases and we feel more confident about a lesion dealt with in this manner than in any other because the infective area has been removed from the brain. There is no chronic or quiescent cavity left which may light up in the months or years to come and cause further trouble. Webster, Schneider and Lofstrom extirpated completely an encapsulated posttraumatic abscess obtaining primary wound healing. Kahn admits that "it is now an accepted fact, that the better encapsulated an abscess the easier its successful drainage or excision." It seems however that actually he does not remove them, even when the abscess has such a thick capsule that its upper pole must be excised before a thorough drainage is instituted.

Sachs reviewing his experiences with brain abscesses 6 of which were excised *in toto* and cured says that no unencapsulated abscess should be drained and that during the acute stage penicillin is an invaluable aid in bringing about encapsulation. Aspiration except in cerebellar abscesses should be used only as a palliative procedure until more radical treatment can be instituted. In conclusion he states that excision without drainage is the ideal procedure although he adds that "frequently marsupialization must be resorted to if in the course of an excision the abscess has been ruptured. According to Fincher who reports his 5 cases of abscess (1 cerebellar) cured by removal *in toto*. The results thus far have been such as to suggest that the basic

surgical principle of incision and drainage in the treatment of certain abscesses of the brain might be replaced by total abscess dissection and primary wound closure.' Finally Le Beau advocates the principle of complete extirpation of brain abscess in one stage whether acute or chronic. With penicillin this is possible according to him, in most cases without the development of meningitis even though it may require opening the abscess and often the ventricle. Of his 17 patients thus treated, 3 died. They were all operated upon before the era of penicillin. Of the 14 patients who were cured penicillin was used in 13 and in 1 case no penicillin was used. In acute abscesses that is before the encapsulation he turns a flap, opens the dura, and removes not only the abscessed zone but also a large area of contiguous inflammatory and edematous white matter. Thirteen of the 17 abscesses were chronic and 4 were acute.

The review of the literature shows so far that there are on record 52 cases of total removal of brain abscess. In about half of the cases the lesion was diagnosed properly before the operation in the rest the abscess was taken for brain tumor and excised as such. Of those 52 patients, 8 or at the most 9 died after the operation while all others recovered and in no case did the removal of the abscess reactivate the inflammatory process. It should be re-emphasized that the fear of such a complication represents the main reason why so many who theoretically consider radical treatment as the most rational do not practice it more often.

PERSONAL OBSERVATIONS

Our personal observations deal with 43 cases of cerebral abscesses. In 33 instances the patients were operated upon in the Neurosurgical Service of Neurological Clinic University of Warsaw in 4 in the Hospital of the Good Friars in Cracow and in 6 in the Neurosurgical Service of the Neurological Clinic University of Cracow. In 17 patients the abscess was either drained or tapped and its contents evacuated and in 26 patients the lesion was extirpated radically.

Here, we are interested solely with the 26 patients given radical treatment. In 12 of

those cases the abscess was of traumatic origin in 6, the source of infection was not determined. 5 abscesses were of otogenic origin in 2 cases the abscess developed in connection with osteomyelitis of the skull and in 1 case most probably after erysipelas of the face. In 12 cases the pus contained *Staphylococcus aureus nonhemolyticus* in 2 hemolytic staphylococcus and in 3 nonhemolytic streptococcus. In 9 instances no bacteriological examination of the pus was carried out due to the very difficult wartime conditions of hospital work. These conditions were the reason no autopsy was done on 1 of the 2 patients who died in the hospital after the operation.

Two patients were operated upon 1 month after the infection 5 two months after 6 three months after 1 ten months after 4 one year after and in 8 patients the duration of the disease was unknown. More precise data were obtained as to the duration of symptoms from their first appearance to the time of operation. 1 patient was operated upon 2 weeks after it was clear that the injury of the head which he sustained several months previously had produced a brain abscess. 2 patients were operated upon 3 weeks after the onset of the first signs of the disease. 1 four months after 1 five months after and 2 twelve months after. In 2 patients the duration of the symptoms was unknown.

In 8 instances the cerebral abscess both posttraumatic and resulting from osteomyelitis of the skull was complicated by an active skin fistula. In 9 cases the capsule ruptured during the operation while in 9 cases it was opened intentionally to facilitate the removal of an abscess of large dimensions. Thirteen patients had an abscess more or less deeply located in the white matter and in 12 cases its upper pole was reaching the cortex. In 1 patient whose case history was lost the exact location of the lesion is unknown. In 24 patients the abscess wall was thick measuring from several millimeters to 1.5 centimeters and more in width in only 2 instances was the capsule thin although in 1 patient, the abscess was of 5 weeks and in another of 8 weeks duration.

In 6 out of the 26 cases the abscess was diagnosed before the operation as brain tu-

mor In the remaining cases the diagnosis was accurate. One patient has had 3 cerebral abscesses 4 patients have had 2 abscesses and in the other patients the lesion was single. In 1 case there was a cerebellar abscess in the other cases, the abscesses were located in the cerebrum. Two patients were operated upon twice all others were operated upon only once. One patient left the hospital 16 days after the operation 1 eighteen days after and 3 nineteen days after. Light went home 3 weeks after the enucleation of the abscess, 5 one month 4 one and a half months 1 two and a half months and 1 seventy days after.

Two patients died 1 of these from meningitis for which he was readmitted to the hospital 2 months after a successful removal of a brain abscess. The meningitis developed acutely after the patient who felt entirely well hit a beam with his head. He had been wounded by several fragments of a bomb and only one of these had been removed together with the abscess during the operation. It may be therefore that he had a second abscess unnoticed at the time of operation which ruptured after the trauma and produced the fatal meningitis. The second patient died 2 weeks after the operation with symptoms of streptococcal meningitis. This patient whose abscess followed an osteomyelitis of the skull, had had symptoms of meningitis long before the ill advised operation was performed.

The ultimate fate of 2 patients is unknown although they were feeling well for about 3 years after the operation. Twenty patients recovered fully and were followed up from 2 months to 7 years after the operation. Only 1 patient did not regain the use of his speech lost because of brain destruction at the time of his injury although his hemiplegia improved markedly. Another patient has a permanent hemiplegia. Of the followed up cases in 1 patient 2 months have elapsed since operation in 4 three months in 4, four months in 1 five months and in 1 one year. The rest 16 9 patients were operated upon 1 to 7 years ago. Only 1 of the 9 patients followed up for more than 1 year after the extirpation of the abscess, is still troubled by epileptic seizures which developed almost immediately after his head injury.

The following observations will illustrate some of the problems which one encounters in dealing with a rather typical, uncomplicated cerebral abscess.

CASE 1: B. M., aged 15 years, was referred to the Neurosurgical Service of the Neurological Care, University of Warsaw, on December 29, 1945 (history No. 1774) by Professor E. Herman of Lódz with a tentative diagnosis of brain abscess. In October 1945, the patient was wounded with a knife in the left parietal region of the skull. After a few days, the skin wound healed completely but the patient noted loss of sensation in the second finger of his right hand. One month later, he began to suffer from headaches and a fistula discharging a purulent fluid appeared at the site of the previous skin wound. The fistula closed after several days, but the patient began to complain of attacks of numbness in the right half of the lip, the tongue and in the right hand. Twice the attacks of numbness were followed by loss of consciousness and clonic movements in the right upper extremity. Physical examination showed temperature 36.6 degrees C., pulse 74. In the left parietal region of the skull there was a scar adhering to the bone. The x-ray pictures of the skull showed a small defect in the left parietal bone and in the middle of it, a foreign body the shape of a broken knife. He had no signs of meningitis but had a hyperemia of both optic discs, especially of the left. There was also an astereognosis and loss of sensation of position and movement of the fingers and of the right wrist. Examination of the blood and the cerebrospinal fluid was essentially negative. With the diagnosis of a cerebral abscess in the left parietal lobe the patient was operated upon on January 10, 1946. An osteoplastic flap was turned down with the bone defect in its center. During the breaking of the bone flap the tip of the broken knife was extracted from the scar filling out the bone defect. It was however still in the dura which was adherent to the leptomeninges. The blood vessels of the cortex were seen to be cuffed by a white exudate. The swollen brain was incised parallel to the dura made out of the dura and the leptomeninges and after the abscess, the size of a large plum, located just beneath the cortex, had been dissected free from the surrounding softened brain tissue, the whole mass was removed intact. The brain rapidly filled in the cavity resulting from the removal of the abscess. The dura mater was only partially closed because of the tendency of the brain to prolapse. The bone flap was returned to its place and a rubber drain introduced between the oozing bone and the skin. The abscess wall was 1 centimeter thick, the pus dense and greenish. Unfortunately there was no bacteriological examination of the pus.

The patient withstood the operation well having only a transient paresis of the right upper extremity and a motor aphasia. In the evening, the temperature rose up to 39 degrees C., the following evening descending down to not more than 37.5 degrees C. The fourth day after the operation the sutures were re-

removed and the wound found to be healing by primary intention. However 3 days later the skin opened in one place and there was a cerebrospinal fistula which closed after 1 week. On February 5, 1946, twenty five days after operation the patient left the hospital feeling well. Sixteen months later he is well and working and except for an asterognosis of the right hand has no signs or symptoms of his previous disease.

The patient was operated upon 3 months after the head injury and 8 weeks after the appearance of the first signs of the abscess. Under these circumstances we felt sure that it would be already well formed and firmly encapsulated. Our supposition was confirmed. Sixteen months have passed since the operation and we feel therefore that we are entitled to presume that the removal of the abscess did not cause an inflammatory process to flare up which might eventually persist in the vicinity of the abscess. In 16 months this would certainly have betrayed itself by some symptoms.

The brain tissue about the abscess was markedly softened a finding frequently observed in these lesions. However this is by no means an indication of an active inflammation about the abscess. Quite the contrary these changes as pointed out by Penfield (41) spreading sometimes in both hemispheres may be quite unassociated with encephalitis. The perivascular exudate seen in the cortex of this, as of many other patients may be according to Penfield (41) the only superficial evidence of a brain abscess when it is situated deeply in the brain. The exudate is the expression of the work of macrophages which are discharging both here and in the white matter the products of disintegration of the brain tissue.

Neither the blood nor the cerebrospinal fluid of the patient showed any signs of abnormality. This is in agreement with the experiences of many observers in cases of encapsulated cerebral abscesses. Woltman who studied the problem of the changes in the cerebrospinal fluid in cases of brain abscess has come to the conclusion that once the purulent encephalitis is localized and encapsulated the polymorphonuclears disappear from the fluid and their place is taken by the lymphocytes. A small number of lymphocytes would seem

on the whole to indicate better encapsulation, greater resistance and a smoother convalescence after operation. The persistence or reappearance of neutrophils suggest that encapsulation is not progressing satisfactorily. As is well known leucocytosis of the blood disappears in later stages of brain abscess either completely or is greatly lowered. A high leucocytic count in the blood suggests rather strongly that the purulent encephalitis has not been fully localized and walled off.

There were also no choked discs, the optic papillae of our patient being only slightly hyperemic. This too is in accordance with the experience of others. The presence of a papilledema is not necessary for diagnosis of a brain abscess. On the contrary, a high grade papilledema points to the fact that the encephalitis is still progressing or that the abscess is accompanied by serious swelling of the brain (32). The best time for operation is when the choked discs if present at all become stationary whereas when the papilledema is advancing the operation is usually dangerous.

CASE 2. H. W. aged 22 years was admitted to the Neurosurgical Clinic, University of Warsaw, on January 28, 1942 (case history No 966). Three weeks previously the patient had been hit with a knife in the left parietal region at once losing the power in his right extremities. The skin wound healed in 3 days, and 1 week after the injury the paralysis of the right lower extremity began to subside. However 2 weeks later he complained of headache, nausea and vomiting and the right lower extremity became once more paralyzed. The physical examination showed temperature 37.2 degrees C, pulse 50. There was a scar in the left parietal region of the skull but the x-ray pictures of this showed no fracture. The patient had no symptoms of meningitis but a slight papilledema, paresis of the right lower facial nerve, a complete paralysis of the right upper and a distinct paresis of the right lower extremity were present. There were no sensory changes, no aphasia, and reading, writing and counting were normal. The blood contained 9,050 white cells. There was little doubt but that the patient was suffering from brain abscess there was however some difficulty in determining its precise location so made. When attempting to puncture the left lateral ventricle in the occipital region a resistance was encountered at a depth of about 5 centimeters. After it was forced some 30 cubic centimeters of semifluid chocolate-colored nonodorous matter were aspirated through the exploring needle and then the cavity was

filled with air. The air was introduced also into the right lateral ventricle. The x ray pictures revealed in the left parieto-occipital region of the brain, a cyst measuring 2 by 2.5 centimeters and a dilatation of the right lateral ventricle which was slightly pushed laterally. The bacteriological examination of the contents of the cyst showed nonhemolytic streptococci. The abscess wall being very thin, there was of course no question of total removal of the lesion. It was decided therefore to wait for the firm encapsulation of the abscess and in the meantime should the condition of the patient call for it to aspirate it. This was done twice: once on February 17, 1942 and the second time on March 2, 1942. On the first occasion some 30 cubic centimeters of the same chocolate-colored matter containing nonhemolytic streptococci were evacuated whereas on the second only a few cubic centimeters of thick yellow pus which unfortunately was not examined bacteriologically were obtained. Between the first and the second puncture of the abscess the leucocytosis in the blood descended to 4,200 cells. The headaches, nausea and vomiting disappeared while the paralysis of the right extremities, especially of the arm, was slower to subside.

Finally on March 12, 1942 nine weeks after the injury and 7 weeks after the appearance of the first signs of the disease the patient was operated upon. An osteoplastic flap was turned down in the left parieto-occipital region and an abscess the size of a large walnut, found 3 centimeters beneath the cortex. Its capsule was thick and elastic. The consistency of the brain tissue around the lesion resembled that of an oligodendroglioma. With the aid of the sucker the abscess was dissected free from the brain and the capsule extirpated intact.

The postoperative course was uneventful, although once more there was a complete paralysis of both right extremities. The temperature after the operation was never higher than 38 degrees c. The cerebrospinal fluid examined 24 hours after operation was found to be sterile. On April 3, 1942 that is, 22 days after the abscess had been removed the patient went home feeling very well subjectively. Objectively there was complete subsidence of the papilledema and of the paresis of the right lower facial nerve and the paralysis of the right extremities was distinctly improving. During the first 3 years after operation, the patient felt well and was working. Later we lost track of him.

In spite of the fact that the abscess, situated 3 centimeters beneath the cortex and containing streptococci was tapped three times and then removed, there was no reactivation of the infection of the brain. The main reason for that is the resistance of the body to the organisms which provoked the original infection.

Since the first symptoms, i.e. paralysis of the extremities appeared immediately after

the head injury the symptoms of brain abscess following 2 weeks later it may be presumed that the first sequel of the trauma was an intracerebral hemorrhage which later became infected. This infected hematoma was finally encapsulated so that in the end we were dealing with a brain abscess proper. It is of course difficult to see what the method of invasion was in this case. Infection of a thrombus of some of the venae communicantes or a metastasis from a distant source? The skin wound healed 3 days after the injury and there was no osteomyelitis. It may be, therefore, that the infection of hemorrhagic focus came either from a latent otitis or sinusitis, or that it came from some distant source. The fact, however, that the paralysis of the extremities appeared immediately after the injury as well as the chocolate color of the pus point rather conclusively that the primary lesion was an intracerebral hemorrhage.

As is well known circumscribed intracerebral hematomas often diagnosed as brain tumor are by no means a rarity. Knickel dealt with them extensively. The gliosis of the brain found in this case about the abscess, presents another argument for the assumption that the original lesion consisted here in an intracerebral hemorrhage. However it must be added that instead of softening of the brain tissue around the abscess one may sometimes encounter gliosis and giant cell formation, especially when the abscess is well tolerated. Such changes may sometimes be seen throughout one or even both cerebral hemispheres (41).

When the diagnosis of brain abscess was made the capsule of the abscess was still very thin so that it could be tapped only. Had symptoms of intracranial hypertension been more severe or had they not subsided after the first aspiration we would have made a decompression followed by repeated aspirations. Yet even if this had contributed to the disappearance of the disease we would not have been satisfied but would have tried later to excise the capsule. We would have done this from fear that the capsule left in situ might provoke epilepsy.

CASE 3. K. S., aged 20 years, was referred to the Neurosurgical Service of the Neurological Clinic

University of Warsaw on January 5 1946 by Dr K. Kessel from Sochaczew because of aphasia and Jacksonian seizures resulting from a craniocerebral injury sustained 10 days previously. He was hit in the left frontoparietal region of the head by a blunt instrument he did not lose consciousness and felt quite well for 3 days. Then he had his first seizure of 'movements' in the right extremities. In the hospital in Sochaczew he had two similar attacks recognized as Jacksonian seizures. After the second seizure he lost the power in his right upper extremity and he became totally aphasic. For 3 days before admission he had been complaining of frequent vomiting. On admission, the neurological examination showed temperature 37 degrees C pulse 56 and in the left frontoparietal region of the head, near the midline a small longitudinal scar covered by a coagulum of a yellow fluid. X ray pictures of the skull revealed no fracture. There was a complete motor aphasia a papilledema on the left hyperemia of the right optic nerve, a paresis of the right lower facial nerve some rigidity of the neck, a complete paralysis of the right upper and a definite paresis of the right lower extremities. The cerebrospinal fluid contained 1.6 per cent of protein and 190 cells 61 per cent of which were polymorphonuclears and 39 per cent lymphocytes. There was no leucocytosis in the blood. After the admission the condition of the patient, who was somnolent confused and soiling his bed, began to deteriorate. Therefore it was thought advisable to do a large decompression of the brain exploring the site of the injury inasmuch as the possibility of a subdural hematoma could not be excluded. On January 11 1946 a large osteoplastic flap was turned down over the left frontoparietal region of the brain. The dura mater which was very tense and did not pulsate was adherent near the midline in the leptomeninges. The brain was swollen anemic and the majority of the cortical blood vessels were cuffed with a white exudate. When the adhesions between the dura mater and the brain were gently ruptured the cortex broke open in one place and began to discharge pus. This was immediately removed by suction and when the whole abscess cavity was apparently empty almost the whole area of the exposed brain fell in. Since the hole in the cortex through which the pus was aspirated was not larger than that which would be left by an exploring brain needle we confined ourselves to what had already been done the whole procedure amounting therefore to a large decompression of the brain with opening of the dura mater and evacuation of the pus. Bacteriological examination of the pus showed that it contained *Staphylococcus albus*. The postoperative course was at first uneventful and although the patient, who was receiving sulfonamides had a temperature rising to 39 degrees C. his general condition was improving. He gradually improved and ceased to soil his bed. The cerebrospinal fluid examined a week after operation contained only 3 cells and 0.165 per cent of protein. However, 8 days after the operation he had his first bout of high temperature rigidity of the

neck, somnolence and then 18 days later a second bout. Blood examination showed a leucocytosis of 13 950 the cerebrospinal fluid was sterile. We punctured the abscess cavity but found no pus. Unfortunately the skin incision through which the abscess was tapped would not close and a brain prolapse developed. Coincident with that the paralysis of the right upper and the paresis of the right lower extremity began to subside and in 2 weeks disappeared completely. Daily dressings and lumbar punctures brought the prolapse to healing so that on April 13 1946 that is 3 months after the operation the patient could leave the hospital, still aphasic but feeling otherwise entirely well. He had no leucocytosis and the cerebrospinal fluid was normal. Since his operation he has had no epileptic seizures.

He went home without any signs or symptoms except aphasia, yet he was warned that he might suffer from epilepsy both because of his original brain injury and because the abscess wall had been left *in situ*. He was of course advised to take luminal.

For about one month and a half the patient's condition was very good but then the epileptic seizures reappeared both generalized, and also confined to clonic movements of the right half of the face and the right extremities. The generalized attacks with loss of consciousness occurred once a week whereas the Jacksonian seizures, starting always with turning of the eyes to the right, returned more frequently lately even several times a day. Since the operation he had been taking 1 gram of luminal daily. He was readmitted on October 3 1946 nine months after the evacuation of the abscess the neurological examination revealed nothing abnormal except for motor aphasia which was not improving at all. The examination of the blood and the cerebrospinal fluid was essentially negative.

Assuming that the aggravation of the patient's epilepsy was due to the presence in the brain of the capsule we decided to excise it. Consequently on October 10 1946 the skull was reopened and a brain scar the size of a large plum, consisting of connective and gliotic tissue excised. During the excision the left lateral ventricle had to be opened, the cicatrix reaching down to its upper wall. The postoperative course was again at first rather stormy, the patient having a temperature over 39 degrees C. His right upper extremity once more became paralyzed and the lower distinctly paretic. The cerebrospinal fluid examined several times was found on all occasions to be sterile but containing up to 1 720 white cells (80 per cent polymorphonuclears and 20 per cent lymphocytes) and 3.3 per cent of protein. There was no leucocytosis. This state of affairs lasted for 3 weeks and then definitely improved although the skin incision opened in one place and there was a cerebrospinal fistula which closed only after several days. The paralysis of the right upper and the paresis of the right lower extremity began to subside and the patient felt subjectively well. In spite of the sterility of the cerebrospinal fluid we thought it safer to treat him with sulfonamides and

penicillin. He received therefore some 1,600,000 units of penicillin and a thorough sulfathiazole treatment. On November 16, 1946, six weeks after the excision of the scar, he left the hospital feeling entirely well. He was of course aphasic but the power in his right extremities was improving distinctly. He has had a minor attack in his right upper extremity only once during the 7 months which have elapsed since his operation. He was receiving 0.5 gram of luminal the same amount as before the scar excision.

It is of course much too early to say anything about the end result of scar excision in this patient; there is however no doubt that so far since his operation he has had practically no attacks whereas previous to the operation with the same dose of luminal they were very severe and occurred daily. Of course epilepsy may, as pointed out by Pennybacker, an otherwise good result in cases of brain abscess however treated and all of these cases should be kept on regular sedative treatment for several years after operation. Yet it seems to us that leaving the capsule *in situ* will not improve matters but certainly add to the irritation of the damaged brain.

CASE 4. S.M. aged 20 years, was referred to the Neurosurgical Service of the Neurological Clinic, University of Warsaw, on November 14, 1943 (case history No. 1750) by Dr. J. Kalisz, of Lodz, with a tentative diagnosis of brain abscess. One year previously the patient had had erysipelas of the left half of the head and the face accompanied by symptoms of general toxemia and meningitis. He remained seriously ill for some weeks and after that complained of headaches localized in the left temporal region. One month ago his temperature rose, the headache became more severe and he complained of nausea. In the hospital in Lodz, a bilateral papilledema, signs of meningitis, a motor aphasia and a leucocytosis in the blood and in the cerebrospinal fluid were found. After a thorough treatment with sulfonamides the general condition of the patient improved greatly yet the choked discs and motor aphasia remained. On admission to the Neurosurgical Service the patient was confused, had a temperature of 36.8 degrees C., pulse 60, a definite sensitivity of the left temporal region to percussion, a bilateral papilledema, no signs of meningitis, a dilatation of the left pupil, paresis of the right lower facial nerve and of the right upper extremity and a definite sensory aphasia. The cerebrospinal fluid containing 0.66 per cent of protein and 26 lymphocytes in 1 millimeter and showing positive globulin reactions was sterile. There were 9,750 white cells in the blood. The patient was operated upon on November 23, 1943, with the diagnosis of an abscess in the left tem-

poral lobe. After an osteoplastic flap had been turned down and the dura, strongly adherent to the leptomeninges over the posterior parts of the temporal convolutions incised, an abscess was found some 3.5 centimeters underneath the cortex, the size of an apple. It was easily dissected from the surrounding softened brain tissue. However during the removal of the abscess its capsule ruptured so that the pus had to be aspirated. Only then was the capsule extirpated. However there was another abscess, somewhat smaller beneath the first abscess, and located a little posterior to it. It was removed without the capsule being incised. The brain, which had a tendency to prolapse, fell in so that there was no difficulty in closing the dura. The cranium of the brain was filled out with Dakin's solution. The patient who withstood the operation well had an eventful recovery. For 4 days he was treated with penicillin given intramuscularly and 3 days later he was afebrile. The paresis of the right upper extremity and the motor aphasia subsided 3 days after the removal of the abscess and on December 17, 1943, twenty-four days after operation, he was able to leave the hospital with only a slight paresis of the right lower facial nerve.

Until the middle of April 1946, that is, for 4 months, he felt well; then one day the headache in the left temporal region reappeared and he developed a paresis of the right extremities. The site of the decompression became tense, the skin incision opened in two places and began to discharge a purulent fluid. He was therefore readmitted to the Neurosurgical Service on May 9, 1946 (case history No. 1815). The physical examination showed at that time a temperature of 37 degrees C., pulse 68. The patient was psychically clear without disturbances of speech. The bone flap was somewhat elevated and did not pulsate. There were two small purulent skin fistulae in the line of incision covered by coagulated pus. He had no symptoms of meningitis but had a papilledema, especially on the left, a distinct paresis of the right lower facial nerve and of both right extremities and a hypoesthesia over the right side of the body. The cerebrospinal fluid was sterile. There was no doubt that the patient was suffering from a third brain abscess which had either existed at the time of the previous operation but gone unnoticed, or had been provoked by infection of the operative wound. Since a precise localization of the lesion was definite, ventriculography was carried out on May 21, 1946, the x-ray pictures of the skull showing definite compression of the anterior horn of the left lateral ventricle. In view of the diagnosis of cerebral abscess in the left frontal lobe the patient was reoperated upon. The two skin fistulae, underneath which some small bone sequestra were found, were excised and the bone flap raised. The dura was tense and did not pulsate. After it had been opened a large abscess, located anterior to the frontal edge of the skull defect, was found. Its posterior pole was covered by the cortex while the anterior pole was lying outside the frontal lobe, adhering strongly to the dura mater. The ab-

was containing some 50 cubic centimeters of thick pus, was with some difficulty dissected free from the dura and finally removed intact. The cavity of the brain was filled out with 10,000 units of penicillin in 10 cubic centimeters of normal saline solution and a rubber drain left for 24 hours. The operation was followed by complete aphasia and an almost complete paralysis of the right extremities. However, the latter subsided after a few days and a week later the patient's speech became normal again. The next day after operation, a second dose of 10,000 units of penicillin was introduced into the abscess bed and on the third postoperative day 10,000 units of penicillin were given intrathecally. One week later the patient had no temperature and both penicillin given intramuscularly (25,000 units every 3 hours) and the sulfonamides were stopped. The bacteriological examination of the pus of the third abscess showed the presence of *Staphylococcus aureus*. The cerebrospinal fluid examined three times during the patient's stay in the hospital was always found to be sterile. On June 6, 1946, nineteen days after the second operation the patient returned home feeling well and with no signs or symptoms of his disease. When seen 10 months after the removal of the third abscess he was found to be completely well.

Unfortunately the pus from the two abscesses removed at the first operation was not examined bacteriologically. We suppose however that these two abscesses resulted from infection of the brain by streptococci which previously caused the erysipelas. The third abscess extirpated at the second operation was due to staphylococci which certainly caused the osteomyelitis of the skull also. Both the osteomyelitis and the brain abscess found at the second operation resulted most probably from wound infection at the time of the first operation. In all events the third abscess containing staphylococci could not be a result of erysipelas produced by streptococci. Case 3 of Vincent David and Ashkenazy (53) is somewhat similar to our Case 4 inasmuch as they too found two abscesses in their patient at the first operation while at the second performed sometime later they encountered a third abscess. Their third abscess also resulted from infection but whereas in our patient the infection came most probably from outside in their case the recurrence of the abscess was due to the fact that they left a portion of the capsule of one of the abscesses at the first operation. The thickness of the wall of their third abscess was almost the same as that of one of the two re-

moved 3½ months previously. They believe therefore, that the thickness of an abscess wall depends more on the individual reaction of the body to the pathogenic organisms than on the duration of the disease. We agree with that but with this reservation, that both the duration of the disease and other factors are playing an important rôle in this connection. We agree with them not because our third abscess was as thick as the two removed 6 months previously but on the ground of the observations made in other cases. After all we do not know that all the three abscesses of our patient did not develop simultaneously. If our assumption that the two first abscesses resulted from the erysipelas is true, then our patient should consider himself lucky, the metastatic abscesses being usually more numerous. In one case of Bergmann (5) of pyemia following gangrene of the bones of the leg, the patient had had 100 cerebral abscesses.

During the removal of one of the first two abscesses the capsule of the abscess ruptured. It is true that the pus was immediately sucked out yet it must be admitted that some of it could have come into contact with the brain. He was treated with penicillin. It is possible therefore that the absence of any serious complications in this case as in 8 other cases is to be referred to the action of penicillin but in 3 other cases in which the capsule was incised during the operation and in which no penicillin was given there was also no infection of the meninges. These last patients were operated on some 3 or 4 years ago and as they are quite well there is no more danger of recurrence of the abscess. The body which has once mastered an infection of the brain by localizing and encapsulating it is apparently quite able to resist a new infection by the same organisms. The experiences of Krause Kahn and Le Beau who during operations for cerebral abscess several times opened the lateral ventricle without endangering the life of the patient seem to support that view.

According to Hamilton Whitcomb and Woodhall the value of penicillin is highest in the stage of encephalitis which precedes an abscess formation. It helps to localize the inflammatory process. It may also play a great rôle in the treatment of brain abscess by pre-

venting the spread of the infection. Finally it may sterilize the pus. Since it is almost impossible for penicillin to pass through a capsule the best way to sterilize an abscess is to inject the drug into its cavity. This may be done in doses of 50,000 to 75,000 units once a day or as was practiced by Shelden, Pudenz, and Craig, doses of 3,000 to 6,000 units given every 3 hours through a small rubber catheter. Besides that the patient receives 50,000 units intramuscularly every 3 hours.

CASE 5. D. V., aged 45 years, was admitted to the Neurosurgical Service of the Neurological Clinic, University of Warsaw, on May 30, 1946 (case history No. 1868). One year previously the patient had been hit in the right frontal region by a fragment of a shell. He lost consciousness for several minutes. After a few days he was otherwise well but had some headaches and at the site of his injury a fistula, discharging a seropurulent fluid, appeared. Some months ago two small bone sequestra emerged through the fistula. For 1 month the headaches became very intense and he complained of nausea and vomiting. Physical examination showed a temperature of 36.7 degrees C, pulse 68. In the right frontal region, some 4 centimeters above the superior ridge of the orbita and almost at the midline, a fistula, discharging pus, was found. X-ray films of the skull revealed a defect here measuring 1 by 0.5 centimeter. The patient showed no signs of meningitis but there was a choked disc on the right, a slight paresis of the left lower facial nerve, a sterile cerebrospinal fluid containing 0.66 per cent of protein and showing positive globulin reactions. There was a leucocytosis.

The patient was operated upon, with the diagnosis of a brain abscess in the right frontal lobe, on June 7, 1946. The edges of the fistula, which were adherent to the borders of the bone defect and to the dura, were excised; the bone defect enlarged to a size of 6 by 6 centimeters, and the dura opened parallel to the edges of the bone defect. Immediately underneath and adhering to it, an abscess the size of a large apple, adhering at the midline to the falx cerebri but otherwise surrounded by softened brain tissue, was encountered. Because of the size of the abscess, it was difficult to extirpate it intact; therefore its capsule was incised and the pus sucked out. The adhesions to the falx were gently ruptured and the capsule dissected free from the brain. The cavity in the brain was filled out with 10,000 units of penicillin in 10 cubic centimeters of normal saline solution and a rubber drain left between the skin and the highly vascularized bone flap. Bacteriologically the pus contained *Staphylococcus aureus*. The next day after operation the temperature was between 37 and 38.2 degrees C, there was a slight rigidity of the neck and some headache. The drain was removed after 24 hours and another 10,000 units of penicillin injected into the abscess bed. Two days later the cerebro-

spinal fluid was withdrawn for bacteriological examination and 10,000 units of penicillin given intrathecally. The fluid was found to be sterile. The temperature rising up to 38.9 degrees C, continued a few days and the patient complained of headache and rigidity of the neck. However, a week later it was well and without temperature, so that both penicillin and the sulfonamides were stopped. On June 23, 1946, sixteen days after operation, he was home without any neurological findings. When seen 8 months later he was found to be entirely well.

Even an active skin fistula is not necessarily a contraindication to removal of an abscess. However, in these cases, the brain should be exposed as little as possible; that is, only by enlarging the already existing bone defect to a size necessary for removal of the capsule. The pus should be previously aspirated. Of the 7 patients who had such a complication of the cerebral abscess, 5 recovered and in the 2 who died the infection of the brain and the meninges was not a result of operation.

The patient was operated upon 1 year ago, so we cannot be sure whether he is completely safe from a recurrence of the abscess. However, we have here an additional proof that total removal of an abscess, complicated by a purulent skin fistula, is not necessarily always followed by an encephalomeningitis.

CASE 6. W. U., aged 27 years, was admitted to the Neurosurgical Service of the Neurological Clinic, University of Warsaw, on December 3, 1946 (case history No. 3105). She gave the following history. In September 1944, she was wounded in the right parietal region of the skull by a piece of shrapnel. She immediately lost consciousness and her left extremities became paralyzed. For the next 7 months the wound discharged a purulent fluid. Six months after the injury she developed epilepsy consisting of attacks of loss of consciousness and clonic movements in the left side of the face and left upper extremity. In September 1946 she was operated upon because of her epileptic seizures; some superficial operation was performed. In spite of that and of the treatment with luminal (0.2 gm. daily) she continued to have seizures which had lately become more frequent. Since November 1946 she had had bouts of temperature rising to 39 degrees C., complained of headaches, nausea, vomiting, and loss of memory.

On admission the patient, who had a temperature of 39 degrees C., a bilateral papilledema, a left hemiparesis with the sign of Babinski, a bone defect in the right parietal bone measuring 3 by 4 centimeters, covered by an unhealthy skin with a purulent fistula, was co-operative. There were no signs of meningitis. Six hours later she became unconscious and there was a marked bradycardia. A diagnosis of brain ab-

les in the right parietal region of the brain complicated by encephalitis was made and the abscess enucleated. The 20 cubic centimeters of thick, greenish pus aspirated from it contained *Staphylococcus aureus*. The condition of the patient next day was only slightly better, she continued to be very markedly stuporous and the heart beat was still very slow. Consequently the region of the lesion was exposed and the abscess extirpated intact. Its capsule was very thick and partially calcified; the surrounding brain more softened than is usual in these cases. The postoperative course was stormy; the skin closure breaking open and facilitating a huge brain collapse. For 4 weeks the patient was very excited and confused and spoke only French. The temperature was 39 degrees C. but there were no signs of meningitis and the cerebrospinal fluid was continually sterile. After receiving about 6,495,000 units of penicillin (20,000 units into the abscess bed, 150,000 units intrathecally and 5,735,000 intramuscularly) and 133 grams of sulfathiazole (by mouth) she was discharged on February 12, 1947 without temperature headaches or attacks, etc. She felt subjectively well; her skin incision had closed completely. When seen 3 months later she continued to be well free from attacks with only the left hemiparesis which had developed after the head injury in 1934 remaining.

Here is the case, our only case, in which the brain abscess was removed in the presence of an encephalitic bout. Undoubtedly the fact that the patient recovered is wholly due to the chemotherapy. What will be the future of this patient? We will have to wait and see but certainly the removal of a rather large abscess and the dissection of this abscess from the surrounding inflamed brain tissue, did not provoke a fatal meningitis. As mentioned Le Beau radically attacks even the acute abscesses of the brain, that is, he treats surgically the acute stage of the disease. Of 3 patients thus dealt with 2 died and 1 recovered. It will be for the future to decide whether success will crown the surgical treatment of purulent encephalitis but the beginning is certainly interesting and promising. It was 11 years ago when King (25) was wondering whether sucking out septic brain material would not one day be utilized in certain suitable cases of suppurative encephalitis or phlegmon of the brain in which there is but little tendency to encapsulate.

GENERAL COMMENT AND CONCLUSIONS

In conclusion the problem of the radical treatment of cerebral abscesses can be summa-

rized as follows. Purulent encephalitis is either mastered by the body which encapsulates the inflammatory focus, or the infection takes the upper hand over the forces of resistance and the encephalitis spreads over one or even both cerebral hemispheres. The second event takes place when the virulence of the organisms is too great for the forces of defense. The surgeon is unfortunately, unable to influence this battle greatly on the contrary all surgical interference at the early stage of the disease was up to now harmful. Maybe the use of penicillin will change matters.

Experimental researches show that the formation of a capsule around the inflammatory focus starts at the end of the first week after the brain has been infected; the capsule becoming mature at the end of the third week of the disease. It then becomes resistant to the exploring needle and only then can one call such a lesion an abscess. However the victory of the body over the infection, resulting in abscess formation is at the end of the third week still too recent and the wall of the abscess is still too thin to allow it to be treated radically that is, to be removed intact. The best time for this is, according to our experience the eighth week after the infection.

During the first 3 weeks of the disease all surgical intervention is usually harmful. If one loses a patient during that period the reason is found in the ability of the body to overcome the infection. At this stage of the disease the causative treatment may consist only of the administration of penicillin which facilitates the limitation of the process of inflammation. Between the third and the eighth week a single or, if necessary repeated aspirations of the pus are sometimes indicated. Such a procedure can even lead to the subsidence of all the symptoms of the disease. Penicillin introduced into the cavity of the abscess arrests, sometimes completely the growth of the organisms. It can be given in doses of 10,000 to 75,000 units for 24 hours or of 3,000 to 6,000 units every 3 hours through a small indwelling catheter. If after single or repeated aspirations of the abscess the symptoms of intoxication and increased intracranial pressure do not disappear a decompression of the brain through an osteoplastic flap may seem to be indicated.

However the capsule of an abscess cured by aspiration or drainage when left behind is apt to produce epileptic seizures some time later. It is in general difficult for us to find the reason why drainage of an abscess should be preferred to its total removal. For we feel that, on the contrary when successful radical treatment of a brain abscess may it be of otitic traumatic or metastatic origin is as safe as drainage and cures the patient more quickly and more completely. Noteworthy also is the almost complete recovery observed in the majority of cases treated radically. This may be due to the fact that most often cerebral abscesses are located within the white matter where they have a tendency to expand the tracts involved rather than produce their actual destruction. After the removal of the abscess the brain edema subsides the circulation improves and function returns. The radical method of treatment is, of course not free from failures but neither are any surgical interventions. At all events neither our own experience nor that of others confirms the fears expressed by some that the act of separation of the capsule from the surrounding brain tissue is dangerous producing a flare-up of the inflammatory process which may be present even about an encapsulated abscess. No doubt such a complication is possible and probably does sometimes happen. The body however usually takes good care of it being at this stage of the disease wholly resistant to the pathogenic organisms which produced the initial infection.

We do not fear the consequences of a premeditated opening or of a rupture of the capsule during the radical procedure although we take great care of course not to let the pus be spread over the operative field. Indeed experience has taught us that even when the pus, containing organisms comes into contact with the brain this is not necessarily followed by its reinfection the resistance of the body being already well established. It must also be added that the pus of a chronic abscess is often sterile or else the virulence of the organisms is diminished. This is said to be the result of encapsulation of the pus. Finally we are not afraid to extirpate an abscess complicated by an active skin fistula, being persuaded that if the patient

has had no widespread encephalomeningeitis before the operation his resistance to the organisms maintaining the activity of the fistula is sufficiently proved. On the other hand it would seem that an infection of the brain or the meninges by organisms other than those which produced the primary lesion, presents a serious complication. Such a complication however is not peculiar to surgical intervention for brain abscess. The use of sulfonamides and of penicillin may still more enlarge the indications for radical treatment of cerebral abscess those two agents being able to remove the chief contraindication to it, which is, namely a concomitant purulent leptomeningitis. That complication is the main reason why all other methods of treatment are usually of no avail.

Strong and diffuse adhesions between the capsule of the abscess and the dura mater make the removal *in toto* very difficult. In such a case the best thing to do is to aspirate the abscess, instill penicillin into its cavity and then after the infection has been brought to a standstill excise the capsule as you would a brain scar. In such cases, Le Beau advocates the removal of the capsule in fragments.

As a rule the removal of an abscess is quite an easy procedure, the brain tissue surrounding the abscess being in our experience usually softened and the capsule poorly vascularized. The abscess is usually dissected free from the brain with the aid of the sucker and then enucleated gently with the finger. Adhesions between the dura and the leptomeninges are closing up of the subarachnoid spaces about the abscess are provoked by electrocoagulation or painting of the meninges with a 5 per cent tincture of iodine. However this is rarely necessary as the subarachnoid spaces are usually closed by spontaneous adhesions. This happens not only in cases of an abscess located superficially but also in those in which the lesion is situated deep under the cortex. One should avoid leaving behind, in the cavity the brain strips of muscle, fascia, and some tissues facilitating hemostasis. We are also careful to remove all of the necrotic brain tissue which is of course, an excellent medium for the growth of micro-organisms. Dakin's solution is used throughout the operation in Ben-

normal saline solution. Before closing we introduce into the cavity in the brain left after the extirpation of the abscess as a prophylaxis 10 000 units of penicillin in 10 cubic centimeters of normal saline solution. The same amount is injected here the next day and the third day after operation. 10 000 units of penicillin are given in 3 cubic centimeters of cerebrospinal fluid intrathecally on the occasion of the withdrawal of cerebrospinal fluid for bacteriological examination. Penicillin is also injected intramuscularly (25 000 units every 3 hours) especially when the abscess follows a still active inflammatory focus in the middle ear or in the sinuses etc. When the temperature falls and shows no tendency to rise for 3 consecutive days penicillin is discontinued. In our patients this was usually done a week after operation so that the average amount of penicillin given to them did not exceed 1 500 000 units. All our patients were also given various sulfonamides most often dibazol in doses of 2 grams every 4 hours for 2 days then 3 grams every 8 hours, or 5 grams every 12 hours. As a rule the abscess bed is not drained but when it was necessary we did drain the cavity using strips of a rubber glove but only for 24 hours. The dura is usually closed completely.

Using this method in 26 cases of cerebral abscesses (including one cerebellar abscess) of various origins we obtained in 24 cases a more or less complete recovery. Two patients died. The operative mortality in those 26 cases in which the abscess had been radically removed was therefore less than 10 per cent. The comparison of these results with the results obtained by us when using simple aspiration of the pus or drainage of the abscess explains why we are now strong partisans of radical treatment. Of the 9 patients in whom the abscess was aspirated only 5 were cured and the other 4 patients died. In 5 of these the aspiration of the pus was made after the brain had been widely exposed in 4 cases through a small burr hole. Of the 8 cases in which the abscess was drained 6 survived and 2 died. In 4 patients the drainage was performed after an osteoplastic craniotomy and in 4 through a small opening in the bone. The operative mortality of these 17 patients was therefore 35.3 per cent, that is, three times greater than the mor-

talidity of the 26 patients treated radically. In both groups of cases the treatment was instituted at almost the same point in the course of the disease.

CONGENITAL ANOMALIES

I RECALL many years ago visiting the office of the medical director of one of the large insurance companies. Three of the secretaries had obvious congenital anomalies. The inquiry was made whether these young women were employed on account of the kindheartedness of the director and from charitable motives. The answer was no—that they were the best secretaries he had ever had and that he believed their defects acted as an inspiration to keep them on the job and always to be polite and courteous. He believed their defects were assets—not liabilities. He further stated that if he had to employ another secretary he would be inclined to search for one with a physical defect.

This incident is cited for the purpose of stimulating those who work to help those individuals affected by congenital defects and to suppress the pessimist who wonders whether it is worth while to devote time, money, study and energy to their relief.

It can be stated with conviction that there are not ten but hundreds or even thousands of individuals leading happy and useful lives who were born with congenital anomalies and whose parents were first told that nothing could be done for them only to find on further inquiry that the defects could be cured or at least much improved.

The advance that has been made in the last twenty five years in treating these conditions is striking. In the first decade of this century the number of patients afflicted with cleft lip and palate who after numerous operations had been performed presented an unsightly scar on a deformed lip and a mutilated palate with defective speech was enormous. Although today these unfortunate results still take place the number is steadily decreasing. On the other hand the number of patients with these defects who after two or three operations present a well formed lip with an inconspicuous scar and a well reconstructed palate that furnishes good function and little or no speech defect is constantly increasing.

Twenty or thirty years ago the cure of a patient with atresia of the bile ducts was unheard of and the recovery of a patient with atresia of the intestine was regarded as a surgical curiosity. Today although the mortality of these conditions is still unduly high the number of recoveries is on the increase.

Due to careful study of embryology and symptomatology intestinal obstruction due to the arrest in the rotation of the midgut can be recognized as a clinical entity and suitable and successful measures adopted for its relief. Likewise some knowledge of embryology is an important factor in the treatment of duplications of the alimentary tract.

Prior to November 1939 no patient so far as I know with esophageal atresia and tracheoesophageal fistula ever recovered. The condition was either unrecognized or the obstetrician and pediatrician alike advised the parents that a fatal termination was inevitable. Since that time many successful operations for this anomaly have been performed. The first patients to recover were subjected to numerous operations with the construction of an anterior thoracic esophagus. As the defect became more frequently recognized and the patients were brought to the hospital earlier and in better condition the operation of primary anastomosis of the two esophageal segments has supplanted the earlier operation except under rare circumstances. The roughly 60 per cent drop in mortality in congenital diaphragmatic hernia which has taken place in the last fifteen years could not have been achieved without the recognition of the feasibility of performing major surgical operations in the first few days of life and in this condition the necessity of selecting this time. It is important to recognize early the anomalies of the extremities and bony structures usually cared for by the orthopedic surgeon. Although these anomalies seldom are a threat to life, their early recognition frequently simplifies the treatment and makes the end result more satisfactory. The success of the treatment of cardiovascular defects which has been so striking in recent years has been made possible only by careful planning, thorough knowledge of the anomalies of the anatomy of the parts and improvement in anesthesia. Although the operations for these conditions are often not undertaken until later childhood many of the same factors are essential for a successful outcome that are required in the more acute emergencies.

The anomalies of the genitourinary tract are numerous and here again an intimate knowl-

edge of anatomy and embryology is important in the diagnosis as well as in their successful treatment. Such conditions as ectopic ureter, double ureter, hydronephrosis due to obstruction of aberrant vessels, hydrometrocolp, exstrophy of the bladder to mention but a few of the defects of these tracts, have all been successfully treated in recent years. However, their successful treatment has been dependent on familiarity with the possibilities, with factors of development, growth and power of compensatory hypertrophy, as well as experience.

I have mentioned here only some of the congenital anomalies which occur and have indicated that over the last twenty-five years or so much improvement has taken place in their treatment. There is still much to be done in this field which is a far larger one than is generally recognized.

In order to solve any problem and, in this instance to improve the lot of individuals handicapped by congenital anomalies, thoughtful planning is necessary. Careful training of the surgeon to cope with these conditions is obviously the first step. As Dr. Gallie pointed out in his presidential address to the American College of Surgeons, "The time allotted to the teaching of anatomy to undergraduates is being so reduced that none but a superman could be expected to acquire any practical knowledge of it. The same statement could be justly applied to embryology. Likewise in medical schools where the teaching of the basic sciences or preclinical subjects is sometimes in the hands of professors who have had no clinical training, or indeed who are not even holders of an M. D. degree, the correlation between their teaching and its clinical application must of necessity be fragmentary. These statements are made not as a criticism of the excellent preclinical teaching but as a suggestion that it obviously needs to be supplemented

and correlated with clinical work. With the multiplicity of subjects taught in the medical school of today probably the only practical way of adopting this plan would be in the post graduate training period. For the surgeon who is caring for the congenital anomalies the desirability of better training in anatomy and embryology is particularly obvious.

The common practice in children's hospitals of having the pediatrician make the surgical diagnoses running the preoperative and post operative care and calling a surgical consultant for the operation only is not a good one. This policy makes of the so called surgeon only a surgical technician or craftsman and the patient necessarily suffers.

Many congenital anomalies require major surgical operations in the first few days or hours of life. The surgeon who undertakes these operations should be familiar with the factors of early development of the infant of his feeding requirements of possible blood dyscrasias of the details of the electrolyte and water balance requirements. All these factors are greatly affected by the operative procedure and should be the responsibility of the surgeon and not of a pediatrician who cannot be familiar with the factors which alter the requirements and are so often very different from what he is used to. These comments are not intended to belittle the merits of the pediatrician but to suggest that he should occupy the more dignified position of consultant in which he can be of great help rather than to have responsibilities placed upon him which he may not be qualified to accept. In an analogous situation in adult surgery it is pertinent to ask if the surgeon relies on the internist to make his diagnoses and accept the responsibility for the preoperative and post operative care.

In the next few decades far greater advances in the treatment of congenital anomalies may

be anticipated than in the decades just passed. However this advance can take place only by having the surgical problems of early life handled by surgeons who are permanent members of the surgical staff of the children's hospitals rather than by occasional visitors for the purpose of performing a single operation. If surgeons take sufficient interest in the surgery of early life to acquire a better training and if they appreciate their opportunities and responsibilities the advance in the near future can be unpredictably great. To the surgeon who uses the monetary gauge as the only measure of success this field should not be recommended. If however the surgeon is satisfied with an adequate but modest income and gains more happiness out of making advances in lowering the mortality and improving the lot of those afflicted with anomalies this field of surgery offers great and very gratifying possibilities.

WILLIAM E. LADD

CONGENITAL ANOMALIES OF THE FEMALE REPRODUCTIVE ORGANS

EVERY gynecologist and obstetrician possesses at least an elementary knowledge of the embryology of the female sex apparatus—the formation of the genital ridge on the anterior or ventral surface of the mesonephros the appearance of the gonadal anlage the invagination of the celomic epithelium to form the muellerian ducts and the later fusion of the lower portions of the two muellerian ducts to form the uterus and most of the vagina while the upper unfused portions become the tubes. Knowledge of these few simple facts makes it easy to understand the mechanism of most of the congenital anomalies which he may encounter in practice. Various portions of the apparatus may be lacking completely (aplasia) or they may fail

to develop beyond the most primitive stages (agenesis) there may be a duplication of various segments or much more commonly there may be a partial or complete failure of fusion of the two muellerian canals. There are of course other possible anomalies affecting the lowermost portion of the vagina and the external genitalia these involving chiefly the derivatives of the urogenital sinus and often but not invariably being associated with anomalies of the upper or muellerian segment.

In the study of such genital anomalies one should always bear in mind that with them one often finds associated congenital anomalies of the urinary tract such as absence of the kidney, horseshoe kidney, ectopic kidney, or duplication of the kidney. Urography therefore should be a routine part of the examination of all such patients.

With any of the enumerated anomalies the sex characters of the woman as far as her general body development and her psyche are concerned may be typically feminine. Just why the local quirks in the development of the sex apparatus occur is still unknown. On the other hand there is another group of cases, numerically smaller in which anomalies of the sex apparatus are only a part of a more profound genetic disturbance involving those chromosomal factors which give the primary impetus to the development of the organism along male or female lines.

Sex determination dates from the moment of conception depending upon the particular chromosomal pattern of the male gamete. The resulting zygote, therefore, is dominantly male or female depending upon its genic balance, according to the well known theory of Goldschmidt. It is easily possible in some of the lower forms, to disturb and even invert this genetic sex balance and similar disturbances undoubtedly occur in the human. The earlier in embryological development such

extrinsic factors become operative, the more profound the sex changes which result. They are brought about the various forms of true hermaphroditism and pseudohermaphroditism.

While the nature of the disturbing factor is unknown in most cases, endocrinopathies of various sorts such as those associated with certain adrenal cortical tumors, when they develop in fetal or early postnatal life, exhibit at least one type of pseudohermaphroditism. A similar factor becoming operative at a later phase of development would produce a much less profound sex change usually some degree of other of virilism.

I have thought it desirable thus to sketch very briefly the factors concerned in congenital anomalies of the female sex apparatus rather than to try to discuss the latter categorically which would be obviously out of the question in a short communication such as this. While any of the abnormalities above indicated may at times be encountered in practice the most frequent are probably congenital absence of the vagina and usually with the uterus, imperforate hymen, the functional failures of the muellerian ducts, and hermaphroditism true and false.

The treatment of congenital absence of the vagina once a rather formidable problem, has become comparatively easy one is tempted to say almost ridiculously simple. The Baldwin operation so popular in a former day made possible the creation of a vaginal canal which, in my own experience at least, was more nearly perfect than that obtainable by any of the earlier modern methods. But it is no longer a justifiable procedure because of its magnitude and its very real hazard. This is even more true of operations of the Schubert type, in which a portion of the large bowel was utilized.

While even exceedingly simple methods like the test tube pressure plan of Frank, a

used by some and while others still lean to various plastic procedures of the Frank Geist or Graves type in which external skin grafts are utilized it is probable that the most satisfactory method in most cases is that of Wharton either with or without Thiersch grafts of the vaginal tunnel which can usually be so easily dissected out. Even without grafts the results are very satisfactory but the addition of the Thiersch grafts appears to be an advance though it may call for the co-operation of a trained plastic surgeon.

Most of the fusion anomalies of the müllerian duct involve the uterine segment producing all the well known variations designated by such terms as uterus didelphys uterus bicornis unicollis uterus septatus and subseptatus uterus arcuatus etc. Some of these have little practical importance others may give rise to serious clinical problems to either the gynecologist or the obstetrician. In only a minority of cases does the condition *per se* call for treatment but the complications to which it gives rise often do such as the ectopic pregnancy arising in a rudimentary horn or the obstetrical problem which can be produced in at least some cases of uterus didelphys as a result of blockage of the birth canal by the nonpregnant half of the double uterus.

As regards hermaphroditism and pseudohermaphroditism it is gratifying to note the advances which have been made in the treatment of these unfortunate individuals. No longer are they looked upon and perhaps even shunned as freaks of nature but in most such cases it is possible to make the lot of these patients quite tolerable and allow them to live their lives as useful members of society. True hermaphroditism is very rare. Young's compilation (1937) revealed only 9 genuine cases with only a small group since then.

The much more common pseudohermaphrodites are designated as male (pseudoherma-

phroditismus masculinus) or female (pseudohermaphroditismus femininus) according to the testicular or ovarian character of the gonad. This is ordinarily based on biopsy of the latter usually calling for exploratory laparotomy although in some cases one or both gonads are more easily accessible to biopsy since they may be situated in the inguinal canals or in the lateral portion of the external genitalia, the latter especially in the male pseudohermaphrodites with cleft scrotum. All sorts of combinations of either male or female gonads with accessory sex organs of one sex or another may be encountered and many interesting problems of surgical nature thus encountered.

Only a few cardinal principles can be touched upon here. The first and in my opinion the most important is that the male or female sex nature of the gonad plays a relatively unimportant part in deciding the sex to which the patient is so to speak to be socially assigned by the surgeon. Almost never should an adult patient be taken out of the sex category in which she has been raised. The psychologic upheaval which would follow such a step would be enormous and possibly tragic. It is important to know that individuals whose only gonads are testes may be typically female from such standpoints as psychology and libido toward men. Furthermore the local sex apparatus is far more easily conformed to the female type than the male, involving most often the comparatively simple problem of creating an artificial vagina. In many of these cases the clitoris is comparatively small with a urethral hypospadias so that it is simply impossible to convert it into a functioning male organ.

In the second place it should be remembered that the secondary sex abnormalities including the appearance of the external genitalia may often be the same whether the

to develop beyond the most primitive stages (agenesis) there may be a duplication of various segments or much more commonly there may be a partial or complete failure of fusion of the two muellerian canals. There are of course other possible anomalies affecting the lowermost portion of the vagina and the external genitalia these involving chiefly the derivatives of the urogenital sinus and often but not invariably being associated with anomalies of the upper or muellerian segment.

In the study of such genital anomalies one should always bear in mind that with them one often finds associated congenital anomalies of the urinary tract such as absence of the kidney, horseshoe kidney, ectopic kidney or duplication of the kidney. Urography therefore should be a routine part of the examination of all such patients.

With any of the enumerated anomalies the sex characters of the woman as far as her general body development and her psyche are concerned may be typically feminine. Just why the local quirks in the development of the sex apparatus occur is still unknown. On the other hand, there is another group of cases, numerically smaller in which anomalies of the sex apparatus are only a part of a more profound genetic disturbance involving those chromosomal factors which give the primary impetus to the development of the organism along male or female lines.

Sex determination dates from the moment of conception, depending upon the particular chromosomal pattern of the male gamete. The resulting zygote therefore is dominantly male or female depending upon its genic balance according to the well known theory of Goldschmidt. It is easily possible in some of the lower forms to disturb and even invert this genetic sex balance and similar disturbances undoubtedly occur in the human. The earlier in embryological development such

extrinsic factors become operative, the more profound the sex changes which result. They are brought about the various forms of true hermaphroditism and pseudohermaphroditism.

While the nature of the disturbing factors is unknown in most cases, endocrinopathies of various sorts such as those associated with certain adrenal cortical tumors, when they develop in fetal or early postnatal life, explain at least one type of pseudohermaphroditism. A similar factor becoming operative at a later phase of development would produce a much less profound sex change usually some degree or other of virilism.

I have thought it desirable thus to sketch very briefly the factors concerned in congenital anomalies of the female sex apparatus rather than to try to discuss the latter categorically which would be obviously out of the question in a short communication such as this. While any of the abnormalities above indicated may at times be encountered in practice the most frequent are probably congenital absence of the vagina and usually with it the uterus, imperforate hymen, the fusion failures of the muellerian ducts, and hermaphroditism true and false.

This is even more true of operations of the Schubert type, in which a portion of the large bowel was utilized. While even exceedingly simple methods, like the test tube pressure plan of Frank, are

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE second edition of *Gynecological and Obstetrical Pathology with Clinical and Endocrine Relations* by Emil Novak, like its predecessor is written with the clarity characteristic of Dr. Novak's other presentations. The graphic fashion in which the subject matter is described makes it a valuable addition to the medical student's reference bookshelf. The numerous practical clinical observations will appeal both to the general practitioner and to the general surgeon. It is an essential text which should be in the laboratory of every gynecologist and pathologist.

The second edition closely follows the format of the first. The text has been revised to include pertinent new developments accrued since the first edition was published in 1938. More than 100 new illustrations have been added among which are a number of excellent photographs in color of gross specimens. Unfortunately many of the illustrations, notably the photomicrographs, do not compare in sharpness of detail with the descriptions in the accompanying text. Notable innovations have been made in the chapters on endocrinology of the menstrual cycle and in the several chapters on ovarian hormones. Discussions of stromal adenomiosis, mixed mesodermal tumors of the body of the uterus, mesonephroma of the ovary, and hypernephroid carcinoma of the ovary are welcome additions to the second edition. The several pages devoted to diagnostic methods in the chapter on carcinoma of the cervix include a practical and conservative evaluation of the vaginal smear in the diagnosis of cervical carcinoma. Cognizance is taken of the new developments in Rh incompatibilities in erythroblastosis fetalis. The inference that, in some instances, abortion or sterility may be on the basis of an Rh incompatibility is possibly somewhat premature in a text book intended for student use.

The author has admirably fulfilled his own idea of a book as expressed in the preface. He has refrained from making it exhaustive or encyclopedic yet it is sufficiently complete to be of practical value to the clinician and pathologist.

JOHN HUTTMAN

IN reviewing the twelfth edition of *Practical Physiological Chemistry* one is impressed with the re-

markable advances in the field of physiological chemistry during the ten years which have elapsed since the previous edition.

This book is familiar to most medical men for many of whom it served as a text in their first course in physiological chemistry and for whom it has since been cherished as a reference for laboratory methods. The improvement in the text with inclusion of new material which has been progressive with each succeeding edition is particularly notable in the twelfth edition. The book has been largely rewritten; the textual material preceding the experiments or methods given in each chapter has been expanded and wherever possible it presents a clear authoritative statement of present opinion which is invaluable to a student trying to gain fundamental concepts in a new field without being confused by controversial points of view.

As in the previous edition the field of physiological chemistry is covered in thirty-five chapters including a study of carbohydrates, fats, proteins, the various body tissues, digestion, blood, urine, respiratory exchange, energy metabolism, hormones, vitamins and deficiency diseases. A new chapter (Chapter 36) on antibiotics and metabolic antagonists has been added. The chemistry of the penicillins is briefly discussed and two procedures for assay, the paper disk and the serial dilution methods are given. Brief consideration is given to streptomycin, gramicidin and tyrocidine. Under metabolic antagonists is considered a group of compounds with structural similarities but capable of exerting antagonistic effects. The growth-inhibiting effect of sulfanilamide on certain bacteria is reversed by para-aminobenzoic acid. The antagonistic actions of analogues of certain amino acids as ethionine and methionine, β -2 thienylalanine and phenylalanine and of such vitamins as pyridoxamine and thiamine, glucosaccharic acid and ascorbic acid, dicumarol and vitamin K are discussed. The chapter is of more than passing interest to the physician who has not had an opportunity to follow the literature in this special field.

Several other chapters deserve special comment. The chapter on blood and lymph includes a discussion of several newer methods for fractionation of plasma proteins such as electrophoresis, various concentrations of alcohol at low temperatures and by appropriate salt concentrations. In the chapter on blood analysis the subject of photometry is presented in a clear concise manner. This is especially welcome with the adoption in most laboratories of

GYNECOLOGIC AND OBSTETRICAL PATHOLOGY WITH CLINICAL AND ENDOCRINE RELATIONS. By Emil Novak, A.B. M.D. (New York) F.A.C.S. 1941. Philadelphia and London W.B. Saunders Co. 917
PRACTICAL PHYSIOLOGICAL CHEMISTRY. By Philip B. Hawk, M.D. Bernard L. Oser, Ph.D. and William H. Sherman, M.D. 1948. Philadelphia, Toronto. The Blakiston Co. 247

gonads are ovaries or testes. In most male pseudohermaphrodites in which the individuals have lived as women the testes have been removed and in 4 or 5 of such cases including one of my own typical menopausal vasomotor symptoms have ensued. It is probably better to conserve one or both gonads for contrary to popular belief they probably exert no 'contaminating' influence on the life of the patient.

Finally and of great importance is the psychological management of such patients

which may spell the difference between later happiness or unhappiness. They can be treated simply as interesting biological or surgical problems, but as unfortunate human beings with a real cross to bear through life and with sick and tortured minds as well as malformed bodies. Only a physician with real sympathy and understanding in addition to surgical skill and biological knowledge can measure up fully to the particular requirements of patients with this type of problem.

EMIL NOVA.

The comparative anatomy and embryology of the larynx and larynx with numerous colored illustrations are depicted in a manner to command the attention of every laryngologist.

The publishers are to be commended on the excellence of the paper type and illustrations. Truly a magnificent book.

HENRY M. GOODYEAR.

THE book *A Manual of Fractures and Dislocations* by Barbara Bartlett Stimson¹ has been written with the primary purpose of serving as a handbook for medical students and general practitioners. All the essential details of fractures and dislocations are discussed in a brief understandable manner without too much theory or argumentation about disputed points. It is well illustrated with 98 drawings, showing the points discussed in the text.

In order to keep the book in its most simple form elaborate technique and detailed operative procedures are purposely omitted and just as they would only tend to confuse an individual who does not have a background of clinical fracture experience.

A large number of statistical studies are included in the book, compiled from the fracture service of the Presbyterian Hospital of New York City. These figures are very instructive and add materially to the value of the book.

This manual could be most advantageously used by senior medical students and internes during their reparatory training. It would also be an excellent addition to the library of every general practitioner.

CARLO SCUDER.

THE authors of *A Handbook for the Diagnosis of Cancer of the Uterus by the Use of the Vaginal Smear*² state that it was prepared for laboratory use. A careful study of their material and their manner of presentation indicates that not only is it superbly prepared from that standpoint, but also that it contains an excellent discussion of the entire problem of vaginal smears. Their straightforward unbiased appraisal of the value, the errors and the difficulties of the procedure appeal to the reader. The 303 photomicrographs are so well reproduced that this book might well be termed an atlas. All phases of pertinent cellular differentiation are pictured. The magnification and the sharpness of the reproductions are such that cellular detail can be readily visualized. In addition the authors have listed the various types of cells observed under individual headings and give the plate and figure numbers that portray all such cell types. This attention to detail and orderliness on the part of the authors not only makes the study by the reader easier, but also suggests that the same type of thinking is embodied in their entire work.

¹ A MANUAL OF FRACTURES AND DISLOCATIONS. By Barbara Bartlett Stimson, A.B. M.D. Med. & D. F.A.C.S. Philadelphia, Lea & Febiger, 1947.

² A HANDBOOK FOR THE DIAGNOSIS OF CANCER OF THE UTERUS BY THE USE OF THE VAGINAL SMEAR. By Olive Gates, M.D. and Skeels Warren, M.D. Baltimore: Williams & Wilkins Co., 1947.

With this handbook and atlas as a guide, an individual or a laboratory interested in adopting the vaginal smear procedure may save considerable time and effort, make more accurate diagnoses and avoid many difficulties which one would never have supposed existed from a perusal of the many reports on the subject.

JOHN I. BREWER.

THE name Rotunda Hospital, or simply The Rotunda is well known to all obstetricians throughout the world. This unique institution celebrated its two hundredth anniversary this summer in a most elaborate way and I was fortunate enough to have been invited to participate in the scientific part of the celebration. One cannot but be awed by what this old fashioned hospital has accomplished during the past two centuries. This institution has always had two aims, namely to take care of the poor and needy and to teach doctors and nurses. No one can deny that these two ambitions have been and are still being fulfilled admirably. Numerous American physicians are grateful for the training in obstetrics which they received in the Rotunda.

Since the founding of the Rotunda on March 15, 1745 by Bartholomew Morse the work was carried on by such well known names in obstetric history as Ould, Clarke, Labatt, Collins, Macan, Smyly and Tweedy. In recent years glory has been added to the Rotunda hospital by Jellett, Fitzgibbon, Solomons, Davidson and the present master, Falkiner.

Among the great contributions made for the improvement of obstetrics were the fight against puerperal sepsis, the treatment of eclampsia and most of all the emphasis on conservatism in the practice of midwifery. Not enough recognition has been given the Rotunda hospital for its struggle against puerperal fever nor to Tweedy for his contributions to the treatment of eclampsia. As the author points out, Tweedy antedated Stroganoff by one year in his emphasis on the essentials of the conservative treatment of eclampsia. In 1896, Tweedy recommended the control of convulsions by morphine, complete starvation with efficient purgation and the administration of copious fluids. He also approved of the use of stimulants and the removal of blood by venesection when indicated. Prior to the introduction of Tweedy's treatment of eclampsia at the Rotunda the mortality rate for eclampsia fluctuated between 16 and 30 per cent. During Tweedy's 7 years mastership the death rate was 8.6 per cent.

The author of *The Rotunda Hospital 1745-1945*³ O'Donel Browne has done full justice to the Rotunda, but this was to be expected. He has the Rotunda spirit in his blood for two reasons. He was an assistant master of the Rotunda and he is married to the daughter of Tweedy, who was one of the most forceful masters of the Rotunda. The book is not only an accurate historical document but also a scientific treatise. It is delightfully easy to read.

³ THE ROTUNDA HOSPITAL 1745-1945. By O'Donel T. D. Browne, M.B. M.A., M.D. (Univ. D. Sc.) F.R.C.P. (L), F.R.C.O.G. Baltimore: Williams & Wilkins Co., 1947.

the photoelectric colorimeter in place of the visual colorimeter.

The chapters dealing with intermediary metabolism have been enlarged and much improved. Modern views on the chemistry of muscle contraction are very briefly considered and must be read with the section on carbohydrate metabolism to obtain any thing like an adequate understanding of the chemical processes involved.

The text is relatively free from misstatements. Those which do occur are quite evident, as for example on page 431 it is stated that "Experimentally polycythemia may be produced in animals by the use of phenylhydrazine or the use of cobalt salts in the diet." Obviously the reference to phenylhydrazine, if correct, needs further clarification.

In conclusion, this book justly deserves the favorable acceptance accorded former editions to which it unquestionably is superior. The reviewer has found it a text well adapted for use with classes of medical students and feels it should have a place in the library of the physician. He will find in it a ready reference to many diagnostic methods and a clear presentation of current biochemical opinion. The book is well indexed. It is hoped that greater care will be taken in binding the book to its covers in future printings. Aside from this the workmanship is good, and the illustrations both numerous and well done.

CHESTER J. FARMER.

THE BOOK *The Development of Inhalation Anesthetics* by Barbara Duncum presents a careful and detailed history of inhalation anesthesia, beginning with the discoveries of Priestley and Lavoisier through the trials of Long, Newton and associates with ether and of Snow, Simpson and others with chloroform in an effort to find a perfect inhalation anesthetic and method of administration. The important anesthetic problem of the period (1846-1900) was ether versus chloroform, and the era was characterized by alternating periods in which the popularity of one or the other as an anesthetic agent predominated. The Royal Medical and Chirurgical Society of London appointed a committee to decide the question and after animal experiments on the physiological actions of ether and chloroform the committee in 1864 reported that they recommended "mixed anesthesia."

The author concerns herself chiefly with the period 1846 to 1900, and expresses the belief that the social, political, and economic conditions prevailing on the Continent, in England, and America greatly affected the evolution of anesthesia. Only in England had this period been relatively uninterrupted by social, political, and economic unrest, and only in England was the development of anesthesia in the hands of specialist anesthetists, such as John Snow. Elsewhere the surgeon had the final responsibility for the

administration of the anesthetic; he usually used the anesthesia himself and then detailed the occurrence of this necessary but otherwise important task of keeping the patient anesthetized to a medical student or some specially trained person; assistant, often one without medical training. On the side of England research into anesthetic problems was, for all practical purposes, only of academic value as there was little co-ordination or co-operation between the investigators and the surgeon in which chief interest was an insensate and relaxed patient. The result was that on the Continent and in America little real advance in anesthesia was made during this period. The author notes, however, that America after 1866 it was evident that the special anesthetist was gaining more importance and began to stay.

The introduction of the book outlines the development of inhalation anesthesia during the period under discussion and the body of the book elaborates the introductions almost completely in direct quotations from contemporary literature and original correspondence. Many reproductions of illustrations of anesthetic apparatus add to the interest of the book.

The author is a member of the Anfield Department of Anesthetics, University of Oxford, and formerly of the Wellcome Historical Medical Museum, London. These institutions are in possession of the literature and letters from which the detailed, chronological quotations which constitute the bulk of the book were taken.

This work represents much research in accumulating the appropriate material to picture methodically and interestingly the development of inhalation anesthesia during the last half of the 19th century. The fact that the book is not dull but very interesting despite the great amount of detail included, is tribute to the author's skillful tying together of contemporary literature and letters into a unified story.

WALLACE HOBBS.

In the opinion of the reviewer the authors of *His Pathology of the Ear, Nose and Throat* have presented the most valuable text available covering the entire field. The book is beautifully illustrated and direct and practical in its literature—the result of many years of pathological teaching and allied clinical experience.

The sections devoted to comparative anatomy, embryology and numerous sections of the normal and pathological findings of external, middle ear and cochlea, labyrinth, and petrous bone are superlative to the otologist. Manifestations of metabolic diseases, allergy and avitaminosis have been amply covered. The physiology and pathology of the nose and accessory sinuses are carefully described with numerous illustrations (some colored) of changes in the lining membrane of the sinuses.

because of Browne's style of writing it is printed in large type on excellent paper and it is abundantly illustrated. I heartily recommend this book to all individuals interested in the history of medicine and hospitals, and to all physicians interested in obstetrics.

J. P. GREENHILL.

IN a monograph of nearly 300 pages the author of *Anatomia quirúrgica del nervio facial* reviews the surgical anatomy of the facial nerve very completely.

The major portion of the treatise is taken up with original work and essentially with descriptive anatomy based on dissections performed on 16 cadavers. In each case the five separate portions of the facial nerve are studied from its origin to its final distribution. An attempt was made to correlate the final pattern of nerve distribution with the subjects' facial type. Strict correlation seems difficult.

ANATOMIA QUIRÚRGICA DEL NERVO FACIAL. By Vicente J. Bertola. Córdoba, Argentina. Imprenta de la Universidad, 1947.

The second part of the work consists of a very brief review of parotid tumors (a clinical paper on the subject is projected for later publication) and a description of the operative procedures employed by various authors in the management of these conditions. The author's own technique also is described at length.

The text is accompanied by numerous illustrations of semidiagrammatic type. Those illustrating the dissections performed are relatively small. Those in the section of the monograph dealing with the surgical aspects of the problem are clearer however.

The introductory foreword is written by Dr. L. Finocchietto.

This volume affords a source of reference based on original work of detailed character as well as a review of the surgical approaches to exploration in the region of human anatomy where final results may be marred by injury to the facial nerve.

IRIAM T. LAMBERT

COLLECTIVE REVIEW

THIOURACIL AND ITS ALLIES IN THE TREATMENT OF HYPERTHYROIDISM

An Experimental and Clinical Survey

GEORGE M. CURTIS M.D. F.A.C.S., and ROY E. SWENSON M.D., Columbus, Ohio

THE surgical approach designed to control hyperthyroidism has been highly satisfactory in terms of the clinical results obtained. Nevertheless, an adequate medical management is still desirable for those selected patients for whom surgical intervention is for some reason contraindicated, or in whom there remains a persistent hyperthyroidism even after a suitable thyroidectomy. The use of thiouracil and its derivatives has been suggested for such patients. These powerful goitrogenic drugs have also been found of value preoperatively and particularly in patients in whom the sufficient response to iodine has, at times, been questioned. Since these are problems which often confront the surgeon in this field, an extensive review of the experimental background together with the clinical application of thiouracil and its allies has been made and is here presented.

Cheesey, Clawson, and Webster tested the goitrogenic properties of cabbage and other Brassicace in 1928. Later Marine and his associates (134) noted that the administration of acetonitrile produced thyroid enlargement in rats. Iodine, however, prevented this goitrogenic effect. In 1941 the MacKenzies and McCollum, during their study of the effect of sulfaguandine upon the bacterial synthesis of vitamins in the rat intestine, noted

that enlargement of the thyroid gland ensued (131). Richter and Clisby, investigating the effect of bitter tasting substances in rats, found that phenylthiourea induced goiter formation. Kennedy, after studying the Brassicace, suggested that the goitrogenic effect of rapeseed was due to thiourea (112, 113).

In 1943 Astwood and his coworkers adapted a modified thiourea compound, thiouracil, which was found to have powerful metabolism inhibiting qualities (10). After preliminary animal experimentation, Astwood reported clinical improvement of 2 patients with hyperthyroidism following from 1 to 2 weeks of intensive medication with thiouracil (7).

Williams and Bissell subsequently confirmed the clinical applicability of the drug. Since the pioneer reports there have been numerous papers presenting the favorable response of hyperthyroidism to thiouracil (3, 42, 90, 99, 103, 105, 143, 163, 170, 177, 216).

Significant in the early history of thiouracil is the varied response which it received throughout the medical world. At first it was hailed as a panacea which would ultimately displace the surgical management of hyperthyroidism. This enthusiasm, however, was short lived. The pendulum soon swung and rejection even replaced the early acclaim. The widely recognized toxic effects appeared to outweigh its potential value. With the accumulation of more data there now appears to be a more moderate outlook for some thiouracil

From the Department of Research Surgery of the Ohio State University.
This investigation was aided by a grant from the Mary Chittenden Fund for Surgical Research.

vascular than the normal thyroid. The gland may even become fibrous and nodular. Hyperplasia also occurs. The acinar cells increase in number as well as in size. The lumina of the acini are frequently obliterated by the cellular overgrowth. The nuclei of the cells tend to be centrally located. The picture of tall as well as of low columnar cells, general hyperplasia, lymphoid infiltration, and colloid depletion seen as the result of thiouracil therapy closely resembles the changes frequently seen in uncontrolled exophthalmic goiter. With withdrawal of the drug is usually followed by regression of these findings (21, 75, 92, 140, 149, 187, 196). Similar microscopic appearances have been reported in rats after treatment with promizole (95).

The hyperplasia of the thyroid subsequent to thiouracil treatment appears to be due to secondary stimulation of the thyroid by an increased amount of circulating thyroid stimulating hormone elaborated by the anterior pituitary lobe. Thus hypophysectomy prevents the thyroid hypertrophy and hyperplasia normally seen after the administration of promizole (96) as well as other goitrogenic drugs (10, 187). Simultaneous administration of whole pituitary extract and goitrogenic drugs to hypophysectomized animals causes little if any stimulation of the thyroid. Resultant hyperplasia of the thyroid is greater in the normal animal when thyroid stimulating hormone and thiouracil are given simultaneously than when either is given separately (187). Griesbach, Kennedy and Purves (88) attribute the development of thyroid adenomas in rats fed seeds of the Brassicae to stimulation by thyroid stimulating hormone.

Gordon Goldsmith and Chanpiper (84) have noted that an increase in the circulating thyroid stimulating hormone, similar to that noted after subtotal thyroidectomy, is not detectable in the thiouracil treated animal. They conclude, consequently, that the thyroid is largely responsible for the removal of thyroid stimulating hormone from the blood stream. In addition, they have reported that the hyperplastic, thiouracil treated gland has an increased avidity for thyroid stimulating hormone since they found the circulating thyroid stimulating hormone was strikingly and suddenly increased when the goitrous glands were removed. That the circulating thyroid stimulating hormone is increased and that the hyperplastic gland has an avidity for it are also suggested by the work of Larson *et al* (118). These investigators noted that the thyroids of chicks treated with thiouracil have a decreased ability to trap radioactive iodine. However, when thiouracil was withdrawn, they observed that the ability of the glands to trap

radioiodine was greatly enhanced and even approached that of normal thyroids stimulated by thyroid stimulating hormone. The work of Barker (17) again suggests that thyroid stimulating hormone is capable of stimulating the thiouracil treated thyroid gland. He reports a further increase in the size of the glands of thiouracil treated rats and that such rats respond metabolically to thyroid stimulating hormone even though such responses are greatly decreased when compared to those of normal rats. It has also been observed that the pituitaries of rats fed thiouracil present the same picture as do the pituitaries of thyroidectomized rats (10, 129, 130).

Although thiouracil collects in relatively large quantities in the anterior pituitary lobe (38, 187, 212), no reports of a direct stimulatory action of the drug upon the *pars distalis* have been found in the literature surveyed.

Most investigators now agree that the principal action of the thiouracil-like drugs is to prevent the formation of thyroid hormone. This is suggested by the depletion of the colloid in the glands of thiouracil treated animals. Colloid reappears when the drug is withdrawn. The profoundly decreased metabolic response to thyroid stimulating hormone exhibited by thiouracil treated rats (17) is further evidence that thyroid hormone formation is greatly diminished. However the response of thiouracil treated rats to the administration of thyroid substance is within normal limits (16). Thiouracil treated rats respond to thyroid feeding but the response is too irregular to permit the use of such animals for the bioassay of thyroid substance (152).

The amount of thyroxine required to inhibit the production of thyroid stimulating hormone is unchanged by thiouracil therapy (89). Approximately 4.8 micrograms of thyroxine per day are required to restore to normal the metabolic rates and thyroid glands of rats previously given 0.1 per cent thiouracil in their drinking water for 2 weeks (179). Thyroxine or desiccated thyroid given with promizole completely inhibits its goitrogenic properties (95). Small doses of desiccated thyroid administered with thiouracil to patients prevented an increase in size of the goiters so treated (58). The increase in the serum globulin that occurs during thiouracil therapy as well as in hypothyroid states can be prevented or reversed by the administration of thyroid substance (120, 121). Since thyroxine or thyroid substance can prevent the goitrogenic action of the thiouracil-like drugs, it is in all probability true that these goitrogens do not interfere with the utilization of the thyroid hormone once it is formed (94, 132).

like drug less toxic than thiouracil, in the pre-operative preparation of selected patients with hyperthyroidism.

THE METABOLISM AND ACTION OF THIOURACIL

Studies pertaining to the absorption, distribution, metabolism, and excretion of thiouracil are but few. The most comprehensive work to date is that of Williams and his associates (212, 220, 221). These workers report that the drug rapidly disappears from the gastrointestinal tract. It is improbable that all of any given oral dose is absorbed from the digestive tract since gastric juice, the duodenal content, the jejunal content, as well as the staphylococcus aureus and the hemolytic streptococcus are able to inactivate the drug (212, 221). Approximately 15 per cent of the drug given orally is destroyed in the digestive tract (38). Within an hour 50 per cent of a single oral dose is absorbed while a maximum blood level is obtained within from 15 to 30 minutes. Repeated small doses of 0.2 gram every fourth hour maintain blood levels of from 2.5 to 3.0 milligrams per 100 cubic centimeters. When such amounts are given for 3 days and then stopped, the blood concentration falls abruptly and the blood is clear of the drug within 48 hours (212, 221). In the blood stream, thiouracil enters both the red and white cells, but the concentration is greatest in the white cells (126, 127, 187, 212, 221). It is present in high concentration in the serum (221).

Studies by Williamson and his associates suggest that thiourea is readily absorbed from wounds (223). These workers have pointed out that many ointments containing sulfonamides, peroxides, and tannic acid also contain thiourea that has been added as an antioxidant. They observed that when 100 milligrams of ointments containing 1 per cent and 10 per cent thiourea were applied weekly to experimental wounds on rats, thyroid hyperplasia and a great diminution in the amount of stored colloid ensued.

Thiouracil enters most organs and body fluids (187). After administration it is present in large quantities in the thyroid, bone marrow, ovaries, liver and pituitary gland. Smaller amounts have been demonstrated in the kidneys, adrenals, pancreas, brain, heart, lungs, testes, prostate, spleen, and striated muscle. The drug has been found in edema fluid, cerebrospinal fluid, pleural fluid, ascitic fluid, pericardial fluid, urine, and in human milk. The concentration in human milk is 3 times that of whole blood (38, 187, 212, 221). Transfer across the placenta also occurs, and the action of the drug upon the fetal thyroid has been demonstrated (39, 80).

The method or methods involved in the breakdown of thiouracil and its allies in the new organism are obscure. When thiouracil is incubated with liver tissue, 33 per cent is destroyed within 2 hours (212). However, the amount of activation appears to be inversely proportional to the amount of liver tissue present.

The response to a given dose of thiouracil in a rat is greatly intensified after subtotal hepatectomy (212). A similar study to determine the effect of thiouracil after subtotal hepatectomy would be of great interest.

Thiouracil is rapidly excreted in the urine. With 1.0 gram of thiouracil is given orally to a fasting patient, 75 per cent is excreted in 10 hours and 90 per cent within 24 hours (41). The amount of thiouracil excreted as such, however, is variable, but probably varies from 30 per cent (38) to 50 per cent (212, 221). Seventy-five per cent of an oral dose of thiourea has been recovered in the urine of the dog (162). When from 0.1 to 0.3 gram of thiouracil (a common preliminary dose) is given to a normal fasting man, urinary excretion is maximal during the second hour and then gradually decreases. However, as the total daily dosage increases, the percentage excreted per day decreases (187, 212). Cytosine and uracil are detectable in the urine of dogs fed thiouracil (187). Additional studies pertaining to the metabolism of the thiouracil-like drugs are necessary before any comprehensive understanding of their absorption, distribution, and excretion can be reached.

The ability of the goitrogenic drugs to cause thyroid hypofunction is now generally recognized. Depression of the basal metabolic rate in rats fed thiouracil has been reported frequently (17, 14, 152, 179, 192). Growth retardation as well as depression of the basal metabolic rate in rats has been reported after promizole (95) and thiouracil feeding (80). Muhrer and Hogan observed abnormal fat deposition and retarded growth in rats fed thiouracil. Inhibition of amphibian development has also been described (84, 85, 157). Thiouracil treated rats are more able to withstand reduced oxygen tensions than are normal animals (81, 86). Lowering of the basal metabolism in hyperthyroid patients has been reported in almost every paper discussing such instances. A few of these reports may be mentioned (19, 22, 24, 28, 32, 53, 66, 75, 87, 90, 104, 142, 154, 164, 165, 166, 177, 189, 211, 217). Myxedema also occurs after thiouracil therapy (3, 32, 143, 151, 170).

Thiouracil induced changes in the thyroid glands of animals and human beings are strikingly similar. The hypertrophied thyroid, increasing in both size and weight, becomes soft, friable, and more

Fig. 1. The normal reciprocal relationship between the anterior pituitary lobe and the thyroid gland. Thyrotrophin appears to govern the formation and release of the thyroid hormone. The thyroid iodine is normally 2 milligrams per gram of dried gland. The total blood iodine is 4.5 ± 1.5 micrograms per cent. The acetone-insoluble blood iodine is 0.9 ± 0.3 micrograms per cent. The urinary iodine depends upon the intake as well as the geographic region.

Fig. 2. Graves disease—untreated. The normal reciprocal relationship between the anterior pituitary lobe and the thyroid gland is broken by some unknown mechanism. Thyrotrophin appears to accelerate thyroid hormone formation and its release into the circulatory system. The thyroid iodine is diminished (0.5 milligram per gram of dried gland). The total blood iodine and the protein bound blood iodine are increased. The urinary iodine is increased.

goitrogenic groups may interrupt the formation of thyroid hormone at different stages (194)

Campbell and Landgrebe reported that thiourea has a striking affinity for iodine. On the basis of the reaction

they state that 1.4 milligrams of thiourea will combine with 1.63 milligrams of iodine. The reaction is reversible if the concentration of thiourea is above 0.04 per cent. Such a reaction could readily occur when the blood concentration of thiourea is at therapeutic levels. Similar reactions can probably occur with other easily oxidizable goitrogens. This becomes more significant when one considers that the total blood iodine normally averages about 230 micrograms. Salter, Cortell, and McKay (192) have recently reported that thyroid protein continues to be formed by the thiouracil treated thyroid gland. This would favor the hypothesis that the goitrogenic drugs compete with the thyroid cells for iodine. However if the thiouracil-like drugs block only the iodination of the thyroid protein and do not affect the metabolism of des-

iodothyroglobulin they are remarkably specific. Extensive further studies are necessary before the exact action of the thiouracil-like drugs upon the thyroid cell will be definitely known.

Figure 1 presents diagrammatically the normal anterior pituitary thyroid relationship. This appears to be governed by some unknown factor.

A corticothalamic mechanisms may play a role. This aspect of the physiologic relation between the thyroid and anterior pituitary lobe is but poorly understood. There is recent evidence that thyroid stimulating hormone is intimately related to the storage and release of thyroid hormone from the follicles (62, 63, 110, 118, 209).

Figure 2 presents the pathologic physiology of untreated Graves disease. The normal reciprocal relationship of the anterior pituitary lobe and thyroid is presumably broken by the action of some unknown mechanism. As a result the anterior pituitary lobe is stimulated to produce increased thyroid stimulating hormone. Under these circumstances the thyroid is greatly stimulated and manufactures increased amounts of hormone yet apparently cannot manufacture

Barker (15) has made the interesting observation that thiouracil treated rats do not respond metabolically to dinitroresol as do normal rats. He suggested that either the thyroid hormone must be present before a metabolic response to dinitroresol is secured or that dinitroresol acts through the thyroid cells.

The simultaneous administration of iodine with the thiouracil-like drugs does not prevent their goitrogenic action (92 187 192). Larson and his associates (118, 119) have reported that the ability of the chick's thyroid to take up radioactive iodine is greatly decreased within 1 hour of the administration of thiouracil. Chagas, De Robertis, and Couceiro find that the amount of iodine in the thyroid follicle is decreased by thiourea. The alveolar colloid produced under the influence of the goitrogenic drugs is poor in iodine (7 72 98, 178). The thyroidal iodine of rats is severely depleted by administering 150 milligrams of thiouracil per day in food containing 13 micrograms of iodine (192). Thiouracil has been shown to interfere with the incorporation of iodine into thyroxine and diiodotyrosine both in vitro and in vivo (71 73 187). The exact point at which the formation of thyroglobulin is checked has not been established (178). In patients treated with thiouracil, the thyroidal organic and inorganic iodine content diminishes, the circulating protein-bound iodine decreases and the total blood iodine concentration decreases. The urinary iodine excretion first rises and then falls as the body is depleted of iodine. From evidence such as this, it has been concluded that the thiouracil-like drugs prevent the synthesis of the thyroid hormone by the thyroid gland.

That the thiouracil-like goitrogens interfere with some cellular oxidation mechanism is strongly suggested by the work of De Robertis and Goncalves (61). These authors have ascertained the normal oxidation-reduction potential of normal thyroid cells and colloid to be $+0.050$ and -0.200 volts, respectively. Stimulation with thyroid stimulating hormone increases the potential of the colloid to the same level as that of the cells. These authors have also noted that the administration of thiourea both in vivo and in vitro reduces the oxidation-reduction potential of the cells and colloid of thyroid stimulating hormone stimulated thyroids to -0.200 volts. In addition the goitrogenic activity of sulfonamide compounds depends upon the presence in the molecule of a free aromatic amino group or a free aromatic hydroxyl group both of which are easily oxidized (203). Carboxyl and sulfonamide radicals bear but little relation to antithyroid activity.

Astwood, Blasel and Hughes (9) have studied the goitrogenic compounds and have observed that the 2 types of chemical structure associated with antithyroid activity are (1) the thiocarbonyl group, and (2) the aminobenzene group. These, too, are easily oxidizable. The chemical structure of the sulfonamides differs greatly from that of thiouracils and it is probable that the site involved in the mechanism of thyroid inhibition is different (2).

As yet the exact mechanisms by which the thiouracil-like drugs inhibit the formation of thyroid hormone are uncertain. The main hypotheses maintain that the drugs inhibit some enzyme system or systems responsible for the formation of iodination of thyroid protein, or that the drugs themselves combine with iodine in such a way that it is no longer available to the cells of the thyroid.

It is probable that more than one enzyme system is involved in the complicated process of forming the thyroid hormone. The cytochrome oxidase and peroxidase systems were perhaps the first to be implicated (60). Thiouracil was shown to be capable of inhibiting peroxidase (157). Schachner, Franklin, and Chalkoff have reported that the in vitro formation of thyroxine and diiodotyrosine is inhibited by KCN, hydrogen sulfide, cobalt, and NaN_3 . Since only 2 enzyme systems, the cytochrome oxidase and the polyphenol oxidase, are inhibited by all of these inhibitor substances, and since polyphenol oxidase is not present in the thyroid, these investigators concluded that the cytochrome oxidase system was intimately related to the in vitro formation of the thyroid hormone. Paschke and his coworkers (169 171) were able to demonstrate that cytochrome oxidase activity of the thyroid in vivo could be decreased 51-63 per cent by 0.005 molar solutions of thiouracil, but could not inhibit the activity of this enzyme in kidney slices and in bone marrow where it is of the same magnitude as in the thyroid. They also reported that the cytochrome oxidase activity of the thyroid glands of rats fed 0.05 per cent thiouracil in their drinking water for 3 weeks was subnormal. However, Lerner and Chalkoff were not able to inhibit cytochrome oxidase activity with thiouracil. Thiouracil has been found readily to inhibit the in vitro formation of melanin by the enzyme tyrosinase (168) but it exerts no inhibitory action upon xanthine oxidase or inosinephosphate dehydrogenase (187). Since the goitrogenic activity of the cyanoide compounds can be prevented by the administration of iodine, while that of the thiouracil-like compounds cannot (185) it appears that these

Fig. 3. Graves' disease—iodine treated. The normal reciprocal relationship between the anterior pituitary lobe and the thyroid gland is broken by some unknown mechanism. The inorganic thyroid iodine and the organic thyroid iodine are increased. The inorganic blood iodine is increased, but the protein-bound blood iodine decreases even to normal limits. The urinary iodine is greatly increased. The iodine acts in some way to block hormone from the gland, but the

Fig. 4. Graves' disease—thiouracil treated. The relationship between the anterior pituitary lobe and the thyroid gland is further interrupted as the formation of thyroid hormone is blocked. The thyroid gland becomes hyperplastic and the thyroid iodine greatly decreases. The total blood iodine and the protein bound blood iodine decrease. The urinary iodine first increases and then diminishes.

enough to inhibit the production of thyrotrophin. The unknown mechanism stimulating the anterior pituitary lobe appears stronger than the greatly increased circulating thyroid hormone. Thyroidal iodine decreases as the circulating protein-bound iodine rises, and as this occurs the urinary excretion of iodine increases. The patient then goes into a negative iodine balance, unless sufficient supplemental iodine is given.

Figure 3 presents diagrammatically the action of iodine in Graves disease. The increased iodine does not appear to alter the fundamental pathologic physiology of Graves disease, yet it does correct the negative iodine balance. The theory regarding the mode of action of the administered iodine is still controversial, but it is probable that this action prevents the increased release of thyroid hormone into the circulation (63) for a variable period of time. Clinically this is evidenced by the induced "iodine remission" from active Graves disease. Iodine therapy greatly increases the thyroidal iodine, decreases the circulating protein-bound iodine, and results in great storage of iodine (54).

Figure 4 presents diagrammatically the effects of treating Graves disease with thiouracil. The fundamental pathologic physiology remains. As thiouracil is given, the production of thyroid hormone diminishes and eventually ceases. The anterior pituitary lobe thus loses this stimulation with a resultant production of increased thyroid stimulating hormone. Subsequently the thyroid gland becomes even more hyperplastic. Since the ability of the thyroid to take up iodine is greatly diminished by the action of thiouracil, the thyroidal iodine, already decreased by the disease, is further decreased. The circulating protein-bound and inorganic iodine decrease as the urinary iodine first rises and then falls as the organism, already greatly depleted of iodine, is still further depleted.

THE TOXICITY OF THIOURACIL

Toxic reactions, directly attributable to the use of thiouracil, have been reported in from 6.7 per cent (21) to 18 per cent (75) of the cases of hyperthyroidism so treated. The percentage of toxic reactions which may be expected in patients treated with thiouracil is approximately 13.1 as reported by Van Winkle and his associates who analyzed 5,745 cases collected from various clinics. Similar figures of 14.4 (138), 12 (142) and 14.5 per cent (218) have been reported.

Reports of toxic reactions due to simple overdose are few. However reports of toxicity due to idiosyncrasy are increasing at a rapid pace (12, 13, 68, 77, 78, 224, 235, 255, 273, 297, 305, 314,

325). Hypersensitivity reactions are the most dangerous. Most feared is the depression of the bone marrow resulting in diminution of the leucocytes and particularly of the granulocytes.

Various writers have presented different criteria as to what constitutes leucopenia and granulocytopenia. This has made evaluation of the available data difficult. It is suggested that Van Winkle's definitions of leucopenia and granulocytopenia be generally adopted in order to avoid confusion in the further evaluation of goitrogenic drugs. Leucopenia (215) is defined as that state in which the leucocytes number 4,000 or less, and the differential count is normal, while the patient presents no subjective symptoms. Similarly granulocytopenia is defined as that state in which the white blood cells number 4,000 or less, while the differential count reveals a particular decrease in the granulocytes (215). Others, however, have thought that once the differential count shows a decrease in the granulocytes, the diagnosis of granulocytopenia should be made and the drug stopped before the clinical signs of fever, malaise, and pharyngitis become evident. If Van Winkle's criteria were to be generally adopted and all cases so reported, it would appear that the incidence of granulocytopenia induced by thiouracil should increase.

Resultant leucopenia, neutropenia, granulocytopenia, and agranulocytosis are commonly reported. These reactions vary in degree from a slight shift to the left in the entire leucocytic series, that returns to normal even if the drug is not discontinued (224, 226) to severe and even fatal agranulocytosis (68, 122, 155, 173, 197). Many reactions varying between these two extremes have been observed (19, 21, 22, 53, 74, 75, 117, 134, 139, 142, 143, 164, 165, 174, 177, 278, 281, 301, 317, 318, 324).

A leucopenia existing before thiouracil therapy may even disappear during treatment (143), or the drug may convert it into a severe agranulocytosis (318).

Leucopenia has an over-all incidence of approximately 4 per cent (155, 215). According to Van Winkle it accounts for 30 per cent of all toxic reactions, and 23 per cent of the patients with this condition develop agranulocytosis. Gabrielle, Kert, and Soffer (75) report that 9 of 51 patients had a depression of the white cells and of these 6 developed agranulocytosis. Agranulocytosis has been reported after as little as 7 days of treatment (305) after a year of continuous treatment (215) and 6 months after the treatment was stopped (215). The most frequent time for agranulocytosis to develop is between the fourth and eighth weeks

suddenly precipitated within 3 hours when a small dose of the drug was again given. Shrinkage of the spleen in experimental animals to one half or even to one fourth of its normal size has been reported by Baumann and Marine (25). Meuthner and Anderson (149) reported an enlarged thymus which they attributed to thiouracil treatment.

Waller and Charipper established normal values for the electrocardiogram of the rat and then studied the changes induced by thyroidectomy and thiourea treatment. These workers noted an increase in conduction time in thiourea treated animals and a decrease in the conduction time in thyroidectomized animals. Both thyroidectomized and thiourea treated animals showed a decrease in heart rate, but this was more pronounced in the thiourea treated rats in which the rate decreased to two-thirds of the normal i.e. the rate decrease paralleled the increase in conduction time noted in the thyroidectomized animals. Both groups showed a decrease in the amplitude of the T waves, but this was greater in the thiourea treated group.

Rose and McConnell observed a gradual decrease in the cardiac output of patients receiving the drug. Bain reported the case of a patient with hyperthyroidism treated with thiouracil in whom fever profound bradycardia complete atrioventricular dissociation pericarditis, and slight jaundice developed. These alarming developments subsided when the drug was stopped. The complete heart block reported by Bain becomes more significant when considered in the light of the greatly increased conduction time reported by Waller and Charipper.

The development of the lesions of periarteritis nodosa has been reported in both man and animals given thiouracil. Marine and Baumann (133) noted the development of these lesions in rats fed thiouracil for 23, 31, 2, and 365 days. The lesions developed along the path of absorption of the drug from the gut. Such hypersensitivity may be induced by specific thiouracil protein conjugates formed in the gut, or their hydrolytic products which are then absorbed through the lymphatics. Gibson and Quinlan (78) reported the case of a hyperthyroid woman who received 31.5 grams of thiouracil in 35 days. She first complained of joint pain and numbness of the extremities. Jaundice leucoderma, and conjunctivitis then developed. The vibratory sense and ankle jerks were lost and coma and death supervened. Autopsy revealed paraneuritis characterized by intense fibrinoid degeneration and perivascular cuffs of inflammatory cells. The

arteritis was most evident in the liver spleen thyroid adrenals kidney and heart.

Similarly Rich (185) reported the case of a patient with thyrotoxicosis treated with Lugol's solution who suddenly developed fever. Potassium iodide was then administered and the patient developed a high fever skin rash joint pains, lymphadenopathy and splenomegaly. Autopsy revealed periarteritis nodosa lesions in the liver spleen pancreas kidneys testes, and prostate. Hypersensitivity to iodine has long been known, yet idiosyncratic reactions to iodine are rare in hyperthyroid patients.

Knab has used thiouracil in the treatment of angina pectoris on the same basis that total thyroidectomy was formerly done for selected patients with the anginal syndrome. Thyroidectomy decreases the amount of circulating thyroid hormone and thus diminishes the sensitivity of the heart to epinephrine. Experimentally a greater amount of epinephrine than usual is required to cause cardiac death in rats treated with thiouracil and conversely a decreased amount of epinephrine is required to cause death in thyroxine treated rats (181) (187). However thiouracil administration also increases the production of adrenotropic hormone by the anterior pituitary lobe (187). The mechanism responsible for this effect is as yet obscure. Raab reported that 8 of 10 patients so treated were benefited. Ben Asher has noted good results in 7 of 8 patients treated but his best result was in a patient with an associated basal metabolic rate of plus 24 per cent.

Purpuric reactions (66, 218) have been noted. They may be due to an increase in capillary permeability or to a decrease in the number of thrombocytes. The latter has been reported (19).

Basophilic hyperplasia and eosinophilic hypoplasia of the anterior pituitary lobe, similar to that subsequent to thyroidectomy are induced by thiouracil and other goitrogenic drugs (89, 96, 187, 192). The production of the gonadotropic and adrenotropic hormones is increased (120, 187).

Liver damage caused by thiouracil has been reported to vary from a slight jaundice to acute yellow atrophy. Jaundice (13, 19, 52, 77, 151, 198, 201, 205, 217) toxic hepatitis (147, 150) and acute yellow atrophy (188) have all been observed. Meuthner and Anderson have noted jaundice clinically with central necrosis and peripheral degeneration of the hepatic lobules at necropsy (149). However their observations are difficult to evaluate, since their patient died in a postoperative crisis. The mechanism of liver damage by thiouracil is obscure. The cholinesterase activity of liver slices treated with thiouracil is twice normal yet

However we have found no studies pertaining to the duration of life of the granulocytes of patients treated with thiouracil. Thiouracil may affect the release of granulocytes from the bone marrow as well as their maturation (127)

Repeated frequent observations of the patient as well as of his blood cells have been advocated by almost every writer who has reported a series of cases of hyperthyroidism treated with thiouracil. Even this has not prevented the development of agranulocytosis. Once it develops, all agree that the drug should be immediately withdrawn and steps taken to stimulate the bone marrow and to ward off infection. An ensuing infection may precipitate a thyroid crisis (205). Penicillin appears to be the best agent available for combating infection and its use has been recommended (218) as has the simultaneous use of whole blood transfusions (190). Because of the known ability of the sulfonamide drugs to produce idiosyncratic reactions and depression of the bone marrow it is suggested that they be used in the treatment of thiouracil induced agranulocytosis only when the superimposed infection is resistant to penicillin therapy. The use of pyridoxine hydrochloride (43, 70, 140) and of pentose nucleotide has been reported (135).

The administration of liver and folic acid simultaneously with thiouracil, in order to prevent the development of agranulocytosis, has been commented upon both favorably (124) and unfavorably (218) as has the concurrent use of liver alone with the thiouracil-like drugs (125, 136). Daft and his associates gave the L. casei factor to rats and noted minimal protection against the development of agranulocytosis when thiouracil was given. Thyroxine was also ineffective. Palmer (167) has reported that cevitamic acid counteracts the effect of thiouracil upon the bone marrow. Lahey and associates (217) advocate the combined use of penicillin, pyridoxine, and folic acid in the treatment of agranulocytosis. This feared toxic reaction with a reported fatality rate varying from 14 per cent (155) to 26 per cent (225) and even 50 per cent (117) certainly demands the best treatment in our therapeutic armamentarium. Limard and Ricewaxer (127) however have emphasized that the key to recovery is not primarily the treatment directed against the agranulocytosis, but rather the amount of bone marrow damage that has occurred. They have advocated that bone marrow studies be made as an index of prognosis.

Mild, transient anemia has also been observed in rats fed thiouracil (55, 208, 210) nevertheless, bone marrow studies reveal little or no depression of the erythroid series. Warren, who produced

erythroid hyperplasia of the bone marrow by intraperitoneal injections of acetylphenylhydrazine has reported that the respiration of young erythrocytes is relatively unaffected by thiouracil. One report of severe thiouracil induced anemia in 2 patients receiving the drug was found in the literature reviewed (142).

Deaths have been reported by various authors (27, 52, 68, 75, 77, 100, 109, 124, 155, 215, 216). Cope, speaking before the American Association for the Study of Goiter on June 22, 1948, placed the number of deaths due to thiouracil at 77. We can add 1 more.

Other severe reactions due to idiosyncrasy are drug fever (1, 4, 74, 141) and dermatitis (74, 115, 143, 198). Drug fever has an over-all incidence of 2.7 per cent and dermatitis occurs in approximately 3.3 per cent of the patients treated with thiouracil (225). Drug fever with a sudden increase in temperature usually develops after from 10 to 18 days of treatment (138). The temperature falls to normal when the drug is stopped and is most apt to rise again if small amounts of the drug are subsequently given. Purpura (66, 218), maculopapular rashes, macular rashes, urticaria, pruritis and scleroderma (117) have been reported following the use of thiouracil. Both drug fever and dermatitis indicate sensitization of the patient and demand that the thiouracil be stopped lest further reaction occur. It appears probable that thiouracil combines in some way with the proteins of the blood (218) and that antibodies against this combination are formed. This is a likely basis for the sensitivity reactions that are reported.

Myxedema is also one of the complications resulting from continued thiouracil therapy (3, 143, 170) but is reversible when the drug is withdrawn. Administration of thiouracil to rats from the time of birth results in retardation of growth, arrested development, mild anemia, and changes similar to those seen in cretinism (102).

Swelling of the submaxillary glands is a frequent development in patients receiving thiouracil (52, 77, 117, 164, 201, 217, 218). Nummy (164) has also reported enlargement of the parotid glands. Williams and associates (218) have reported general lymphadenopathy. That the adenitis, almost specific for the salivary glands, is an idiosyncratic reaction is suggested by the occurrence of the Mikulicz syndrome in a case reported by Bishop and Rawson. This patient developed fever and swelling of the salivary and lacrimal glands. Bacterial cultures were negative, and there was no response to chemotherapy while thiouracil was given. The condition improved remarkably within 48 hours after the drug was stopped. Recurrence was

the in vitro respiration of liver slices is normal (187). In view of the reports of liver damage caution is advised when giving thiouracil to hyperthyroid patients who already show liver damage as evidenced by diminished liver function tests.

Baummann and Marine (25, 26) reported extensive observations pertaining to the effect of thiouracil upon the adrenal cortex of the rat. They noted that a reduction of the cortex to half of the normal size occurs by the third or fourth month of treatment. All 3 layers of the cortex were decreased in size. Dalton and associates have made similar observations. Atrophy of the human adrenal cortex after death from thiouracil has been reported (149). However no changes of the oxygen uptake of the adrenal slices occur in vitro and the blood chemistry changes of adrenal cortical disease do not develop (187). It has been stated by Baummann and Marine that recovery of the cortex later occurs even if the drug is continued. An infection resulted in cortical enlargement in the presence of an atrophy previously induced by thiouracil. The relation of an increased amount of adrenotropic hormone (187) to these changes is not clear. In vitro concentrations of thiourea as low as 6×10^3 to 10^4 molar inhibit the stimulatory effect of from 2 to 10 micrograms of epinephrine per liter of glucose tyrode bath on the gut and rabbit uterus. The addition of plasma or red blood cells to the tyrode bath prevents this inhibition. However doses of from 10 to 200 milligrams have no effect upon the autonomic mechanisms of the intact rat (64, 187).

Thiourea appears in mother's milk and also passes the placental barrier (80, 102, 197). Goldsmith, Gordon and Chanpper (80) have given pregnant rats 0.5 per cent thiourea in drinking water for from 1 to 15 days before parturition. They observed that hyperplasia of the fetal thyroid and retarded growth were transient. However the 15 day period of treatment was probably too short to deplete the maternal thyroids of thyroid hormone. These same observers (85) have noted that thiourea inhibits the metamorphosis of *Rana pipiens* larvae and also inhibits the stimulatory effect of thyroid stimulating hormone upon the larvae.

Chu has reported that thyroid hormone is necessary for normal gestation in the rabbit, and has demonstrated that embryos of thyroidectomized rabbits are resorbed or aborted, and that the administration of thyroid substance permits normal gestation and parturition to occur.

Davis and Forbes have reported the sudden death of a 21 year old woman during the sixth month of gestation. She had been treated with thiouracil before and throughout pregnancy and was on a maintenance dose of 200 milligrams daily.

No sensitivity was mentioned. The lobes of the fetal thyroid were hyperplastic and showed no evidence of colloid storage. Williams (214) observed no ill effects in 3 infants whose mothers had received thiouracil during the period of gestation.

Thiouracil has been advocated as a measure to control hyperthyroidism during pregnancy (25, 27, 31, 34, 132, 166, 176, 214). However, controlled experiments in which the effects of thiouracil given to animals and human beings during pregnancy were studied are too few. Until such experiences are reported and evaluated, the advisability of prolonged thiouracil treatment during pregnancy remains questionable.

Goldsmith and Harnly (83) have noted that concentrations of from 10 to 125 milligrams of thiourea per 100 cubic centimeters of water are strikingly lethal for the larvae of the ebony black, and sooty mutants of *Drosophila melanogaster*. Fifteen milligrams per 100 cubic centimeters produce 100 per cent mortality of the wild larvae. Goldsmith and Harnly even suggested the use of thiourea as an insecticide.

Deposition of thiouracil in the urinary tract of experimental animals has been reported (25, 207). McGavack and Vogel (144) found renal calculi in rats given 5-methyl and 5,6-dimethylthiouracil. Barr and Shorr (19), Astwood (2) and Williams *et al* (218) have reported hematuria in patients receiving thiouracil. Paschiks and his associates (171) observed that the cytochrome oxidase activity of kidney slices in vitro is not depressed by 0.002 and 0.01 molar concentrations of thiouracil.

Varied disturbances of the central nervous system during thiouracil therapy have been noted. Atkin observed delusional psychoses. Leys reported euphoria after methyl thiouracil, and Hammer has noted somnolence and mental confusion following thiouracil. Delusions and a persecution complex exhibited by a patient receiving the drug were studied by Pearson. Cessation of the drug ameliorated the symptoms, and further dosage precipitated the same psychosis. Loss of the vibratory sense, loss of the ankle jerks, and then coma were observed in 1 patient by Gibson and Quinlan. Haines and Keating, and Hammer have reported myoclonic muscular contractions and muscular twitchings. Cannon observed improvement in anxiety states after thiouracil therapy but the improvement was greatest when there was an associated elevation of the basal metabolic rate. Riker and Wescoe citing the work of Ellis and Root state that the cholinesterase activity of brain slices taken from rats that had received thiouracil is within normal limits. The altered physiology responsible for these central nervous system symp-

toms is obscure. No studies of the brain metabolism in animals receiving the drug were found in the literature reviewed.

Unobserved and less apparent dangers of the thiouracil like drugs are suggested by Bielschow sky who produced cancer of the thyroid gland in rats with the combined medication of 2-acetylaminofluorene and allylthiourea (31). 2 Acetylaminofluorene is a carcinogen which heretofore has not been known to affect the thyroid gland yet when used in combination with allylthiourea, which alone produced hyperplasia of the thyroid follicle cells, cancer results. Purves and Griesbach have reported the development of carcinoma of the thyroid in 2 of 30 rats after prolonged treatment with thiourea. Metastases were found in the thyroid veins and also in the lungs. These authors attribute the malignancy to prolonged stimulation of the thyroid cells by thyrotropin. These reports call into question the safety of the clinical application of the thiourea compounds, particularly in patients with nodular goiter in whom the threat of malignancy is already present in varying degrees. Many reports discussing the various toxic responses are available (19 21 53 75 77 87 142 155 164, 174, 201 211 218 219 225).

A classified list of toxic responses gleaned from the literature follows

TOXIC RESPONSES

Bone Marrow Effects

1. Agranulocytosis
2. Anemia
3. Granulocytopenia
4. Leucopenia
5. Neutropenia
6. Thrombocytopenia

Cardiovascular Effects

1. Heart block
2. ECG changes
3. Pericarditis nodosa
4. Pericarditis
5. Purpura
6. Flushing

Central Nervous System Effects

1. Coma
2. Confusion states
3. Delirium
4. Dizziness
5. Headache
6. Loss of ankle jerks
7. Loss of vibratory sense
8. Nausea
9. Vomiting
10. Persecution complexes
11. Various psychoses

Gastrointestinal Effects

1. Nausea
2. Vomiting
3. Diarrhea
4. Abdominal pain

Liver Effects

1. Acute yellow atrophy
2. Degeneration of hepatic lobules
3. Hepatitis
4. Jaundice

Lymphatic Effects

1. Enlarged lymph nodes
2. Enlarged salivary glands
3. Leg edema
4. Myxedema
5. Decreased size of spleen
6. Enlargement of thymus

Miscellaneous Effects

1. Arthritis
2. Choking
3. Dryness of the mouth
4. Fatigue
5. Hematuria
6. Fever
7. Joint pains
8. Muscular pains
9. Pharyngitis
10. Thirst

Ophthalmic Effects

1. Chemosis
2. Conjunctivitis
3. Decreased corneal reflex
4. Increased corneal reflex
5. Photophobia

Effects upon the Skin

1. Leukoderma
2. Macular rashes
3. Maculopapular rashes
4. Morbilliform rashes
5. Purpura
6. Pruritus
7. Urticaria
8. Urticaria with pruritus
9. Painful subcutaneous swellings
10. Scleroderma

CLINICAL EVALUATION

Many experienced observers have carefully studied the clinical applications of thiouracil. Additional papers confirming its ability to decrease the basal metabolic rate are available (18, 37 38 53 56 65, 67 69 77 79 92 108 122 140 152 158 159 160 161, 165 181 183 184). Leiter *et al* determined the effect of thiouracil upon the hyperthyroidism resultant from functioning metastases of thyroid carcinoma. In one of their patients the cervical thyroid tissue had been radically extirpated. Activity of the metastases in this, as well as in another patient, was demonstrated by radioiodine studies. The administration of thiouracil caused a decrease in the basal metabolic rate, and an increase in the blood cholesterol and in the body weight. The urinary excretion of radioactive iodine was doubled during thiouracil therapy. Recurrence of the hyperthyroidism occurred when the drug was withdrawn. No effect upon the growth of the metastases was reported.

Iodine administration previous to thiouracil therapy causes a slower response to the drug (19 92 151 167 187 214, 217) but does not prevent its characteristic goitrogenic action (58). Some depletion of the thyroid hormone already manufactured and stored appears to occur before

its action becomes evident clinically since thiouracil, soon after its administration decreases the ability of the thyroid to take up iodine (119).

Initially 0.6 grams in 3 divided doses of 0.2 gram each are usually given daily until the basal metabolic rate has fallen to normal limits. Then maintenance doses of from 0.1 to 0.2 gram per day are continued (21 22 29 33 53 56, 69 101 117 151 155 211 217 225). Therapeutic blood levels on dosages such as this vary from 1 to 6 milligrams per 100 cubic centimeters. One day of elevation of the basal metabolic rate for each percent of the basal metabolic rate (21 117). However there is usually an initial lag period varying from 2 to 3 weeks before the basal metabolic rate falls toward normal (52 75). Six weeks of treatment may be required before the basal metabolic rate becomes normal (217). However the response to the drug is slower if the disease has been of long duration (87). A basal metabolic rate

that is high initially may fall rapidly during thiouracil therapy while a low one may fall quite slowly (174). The basal metabolic rate also falls more rapidly in young people (211). Early hyperthyroidism responds more rapidly than chronic. The hyperthyroidism of diffuse hyperplastic goiter responds more favorably than does that of toxic nodular goiter (29, 167, 183, 187). In a relatively small number of patients there is no response to the drug (51, 52, 66, 147, 187, 189). Poate failed to secure a remission of the hyperthyroidism caused by a functioning fetal adenoma with thiouracil therapy.

Other changes in addition to the decreased basal metabolic rate also indicate a reduction in metabolic activity. The blood cholesterol rises (21, 52, 141, 142, 148, 211) and there is a more or less straight line relationship between the elevation of the blood cholesterol and the falling basal metabolic rate (141). It has also been observed that the blood cholesterol may rise to myxedematous levels before the basal metabolic rate decreases to similar levels (16). The protein bound iodine of the blood decreases to normal (117) and its fall may be more rapid than that of the basal metabolic rate (211, 214). These findings we are able to confirm. The excretion of calcium, nitrogen, phosphorus, and creatinine is decreased toward normal limits (19). An increase in the plasma or serum globulin occurs even though the total blood protein may remain unaltered (120, 121). An increase in the plasma chloride and a decrease in the plasma carbon dioxide combining power have also been reported (93). The effects of thiouracil upon the blood magnesium partitions are controversial (35).

Exophthalmos is generally unaffected by thiouracil administration (66, 69, 139, 187). McGavack *et al.* (142) noted no increase of exophthalmos in 38 patients with Graves disease treated with thiouracil. Decreased lid spasm and increased body weight may give the illusion of a decrease in exophthalmos (187). However untoward reactions varying from slight ocular irritation with conjunctivitis and lacrimation (167) to an increase in exophthalmos (19) have been reported (187). Periorbital edema associated with high cholesterol emia has been reported during thiouracil therapy (147). Thyroid substance has been given to prevent untoward ocular reactions (167, 161, 187). Additional accurate ophthalmometric measurements are required before the relation of thiouracil to exophthalmos can be accurately assessed.

Thyroid enlargement, noted subsequent to the feeding of the *Brassicæ* to animals, led to the discovery of the goitrogenic drugs. However there is as yet little agreement as to how much the

human thyroid enlarges or regresses during thiouracil therapy. Apparently the degree of enlargement is not related either to dosage or duration of the treatment (21, 66). Great enlargement, accompanied by a striking increase in vascularity (140) as well as 20 per cent (62) and from 30 to 40 per cent decreases (53) in the size of the thyroid have been observed. Initial enlargement followed by transient decreases after 2 or 3 weeks of therapy have also been reported (142). Watson made measurements of the necks of 35 patients who received the drug and stated that the increase in the size of the neck varied from 0.25 to 1.0 inch and averaged 0.63 inches. Water restriction does not prevent thyroid enlargement in rats given thiouracil (208). The increase in the size of the gland as well as other evidences of goitrogenicity may be prevented by the administration of thyroid substance (58, 89, 95).

Thyroid enlargement induced by thiouracil becomes of major significance when the pre-existing goiter is substernal, retrovisceral, or retrovascular. Severe pressure symptoms due to an enlarging substernal goiter have been reported (206). The tendency for older nodular goiters to undergo vascular degeneration with repeated hemorrhages, together with the ability of thiouracil to cause an increase in the vascularity of the goiter should also be considered whether the goiter is substernal, retrovascular, or simply cervical.

Patients treated with thiouracil often state that they feel better before there is any obvious clinical improvement (142). Tremor, agitation, and perspiration are usually improved before tachycardia is decreased (69). Tachycardia decreases more slowly than the basal metabolic rate (69) and is usually the last sign of hyperthyroidism to abate (99, 187).

A relatively high per cent of remissions of long duration subsequent to thiouracil therapy has not been observed. The ability of any similar drug to maintain decreased thyroid function after its withdrawal would appear to be limited unless it actually destroyed thyroid cells. There are no satisfactory criteria by which to judge the duration of treatment with thiouracil and to determine which patients are most apt to have remissions (139). Six months of treatment before withdrawal of the drug has been advised (6, 204). However McGavack *et al.* (142) have continued treatment as long as 26 months. Williams (214) states that if the initial basal metabolic rate is relatively low and the thyroid relatively small, remissions are more apt to occur than if the initial basal metabolic rate is high and the gland large. He also writes that remissions are more frequent in those pa-

tients in whom the size of the thyroid gland decreases during therapy. Males are more apt to relapse than females. Treatment for less than 6 weeks is usually followed by a relapse within 2 weeks after withdrawal of the drug, treatment for 6 weeks or more usually results in remissions lasting longer than 2 months (20). Relapses are less frequent if treatment is continued for 2 months or longer and are also most apt to occur within 2 months of the withdrawal of the drug (29, 214). After thiourea therapy, remissions are more prolonged if small amounts of thyroid are more simultaneously (58).

Various periods of remission after thiouracil therapy have been observed. Remissions varying from 3 to 21 months (214) from 2 to 7 months (142) from 2 to 11 months (66) from 2 to 15 months (69) from 3 to 7 months (189) and from 8 to 12 months (217) have been reported. Most observers agree that the number of patients followed for a long period after withdrawal of the drug is as yet too small to permit general conclusions (29). Salter and his associates (192) have attributed remissions to a thiouracil hangover effect upon the thyroid cells. However, there is at present no way of determining how long this effect will continue when the drug is discontinued after any given regimen of dosage.

Beierwaltes and Sturgis have re-emphasized the cyclic nature of Graves' disease and have cited Plummer's earlier work which points out that the disease may fluctuate with remissions and exacerbations for from 2 to 4 years before a true remission occurs. It would seem that similar periods should elapse before it could be maintained that a relatively permanent remission was induced by thiouracil.

The cyclic variation of hyperthyroidism makes the evaluation of remissions difficult (191). The many relapses that occur provide good evidence that the effect of the drug may be quite transient once it is withdrawn. There is also evidence that thyroid function may return to and even exceed the normal when administration of the drug is stopped (119, 139).

Diabetes mellitus complicated by hyperthyroidism is benefited by the reduction in metabolic iodine induced by thiouracil as it is by the usual iodine therapy. Revengo (184) noted that the diabetes mellitus was less severe in 7 of 19 collected cases. A decrease in the insulin requirement of such patients was noted by Fishberg and Vorzimmer (66).

The use of thiouracil as an adjunct to the existing means of preoperative preparation of hyperthyroid patients has been advocated by many (21

22, 27, 56, 101, 117, 128, 140, 151, 152, 188, 191, 195, 200, 204, 217). It appears probable that the drug or its allies will find their proper place in the preparation of those patients for surgery who would be very poor risks indeed if prepared by other ordinary methods alone. Here thiouracil should be used as a supplement to the other methods (195) and not as a single therapeutic agent (27).

Many surgeons have noticed that the thiouracil induced hypervascularity often causes a persistent oozing that is difficult to control during surgery. Because of this Bartels (21, 22) advocated the administration of iodine before surgery to cause involution of the hyperplastic gland. This method of preoperative preparation has been most widely adopted and is briefly as follows: — 0.6 grams of thiouracil are given daily until the basal metabolic rate approaches plus 20 per cent and then iodine is administered simultaneously. However, thiouracil is withdrawn about 1 week before surgery and iodine is then given alone. Operation is not advised until the basal metabolic rate is normal and the improvement in symptoms has been maximal (21, 22, 56, 116, 117). Ten milligrams of iodine per day have been found adequate to induce involution in such patients (140). The course during and after surgery has been reported to be more smooth than when thiouracil was used alone (117, 217). Lahey and associates (117) write that this preoperative regimen has all but eliminated the stage of thyroidectomies, and has greatly reduced the mortality among bad risk patients. Montague and Wilson (214) have written that thiouracil will probably find its greatest use in the preoperative preparation of thyrotoxic patients, unless the induced remissions can be maintained for several years after withdrawal of the drug.

King and Rosellini reported that 8 of 10 patients with acute thyroiditis all of whom received thiouracil within 3 weeks of the onset of the disease were given 0.6 gram of the drug daily in 3 divided doses and a subsequent decrease in the body temperature and tenderness of the gland were noted. Two patients that had previously received iodine did not respond. At present there is no understanding as to why the thiouracil therapy was beneficial. The hyperplasia ordinarily induced by thiouracil and its tendency to result in hyperthyroidism are effects that must be carefully evaluated when the drug is given to treat a disease that also tends toward the development of thyroid hypofunction. Additional studies are required before the rationale of thiouracil therapy for such patients can be established.

OTHER GOITROGENS

Thiourea was one of the first goitrogens to be studied extensively (41 55, 58 78, 80 81 86 120 121 187). Clinically, the drug is given in doses of from 1 to 3 grams daily. Its use was discarded because of a relatively high incidence of toxic reactions. Danowski and his associates have recently reinvestigated its clinical use and have reported that much smaller doses than were given previously are effective. The serum precipitable iodine was also decreased by such a regimen. These authors have also advised the simultaneous use of small amounts of iodine and desiccated thyroid.

Astwood and his associates have studied the antithyroid activity of thiobarbital (5 7). Thirty patients were treated and a relatively high incidence of drug fever was observed. Death from agranulocytosis occurred in 1 patient. The drug was given in doses of from 0.2 to 0.3 gram daily. However it is excreted slowly a factor which may account for the increased incidence of toxicity. Bartels (23) has reported toxic reactions in 18 per cent of a series of 28 patients treated with thiobarbital.

Leys treated 19 cases of hyperthyroidism with methyl thiouracil by giving 0.8 gram daily until the basal metabolic rate approached normal limits. Then maintenance doses varying from 50 to 300 milligrams daily were administered. A period of from 10 days to 6 weeks elapsed before the antithyroid action of the drug became evident. Euphoria, eosinophilia, and leucopenia frequently occurred. Drug fever following methyl thiouracil has been reported (206 224).

Williams (213) observed the effects of tetramethylthiourea. In rats goitrogenic activity develops within 14 days, when their drinking water contains 0.04 per cent of the substance. The drug is excreted slowly and relatively high blood concentrations are obtainable. Thirty patients with hyperthyroidism were also treated. Decreases in the basal metabolic rate and blood protein bound iodine were observed, as was also the development of leucopenia and urticaria. Diethylthiourea was administered to 4 patients and the toxic effects were noted in each.

Paraxanthine has been reported to have antithyroid properties (187). However Williams (213) found that it has no effect upon the metamorphosis of *Rana catesbeiana* tadpoles. Likewise, it fails to prevent the increase in oxygen uptake of liver slices such as occurs when these are treated with thyroglobulin. A patient with Graves disease received huge doses of paraxanthine for 11 days and was not benefited. These findings have been confirmed by Barker (15) who gave from 30 to 10,000

micrograms per kilo per day to rats and noted no depressant effect upon the basal metabolism.

Para-aminobenzoic acid decreased the oxygen consumption of rats from 25 to 35 per cent after their drinking water contained 3 per cent for 3 weeks. No toxic symptoms were noted (86).

Higgins (95 96 97) has studied the goitrogenic activity of promizole in the rat and has noted depression of the basal metabolic rate and hyperplasia of the thyroid. This substance is approximately 18 per cent as active as thiouracil (146).

The effects upon rats of 6-methylthiouracil, 5,6-dimethylthiouracil and 2-thio, 4,5-dimethyl-6-methylethylpyrimidine have been studied by McGavack and Vogel (144). These 3 substances are extremely toxic and have a great tendency to cause renal and liver damage. McGinty and Bywater have studied many thiourea derivatives (145) imidazoles (40) and sulfones (146). Pyridine-2-thiol, thiuracil-2-thiol and benzimidazole-2-thiol have goitrogenic properties. Sulfides corresponding to sulfones are more active than the sulfones. Thiourea derivatives have also been extensively studied by Christenson (47). No goitrogenic properties are exhibited by 1,7-dimethylguanidine (15).

Ethyl and also propyl thiouracil have been used both experimentally (8) and clinically (11) by Astwood and his associates. In man, propyl thiouracil is approximately 5 times as effective as thiouracil, and also more active than ethyl thiouracil. The initial dose of propyl thiouracil given to patients was 75 milligrams per day and this was followed by maintenance doses of from 25 to 50 milligrams daily. Propyl thiouracil is now under extensive trial in this and other clinics. Of all the goitrogens thus far studied, it appears the most promising. In 29 patients treated with 6-N-propyl thiouracil, no toxic effects were noted (11).

DISCUSSION AND SUMMARY

Following Astwood's initial announcement of the use of thiouracil in the treatment of hyperthyroidism the thiouracil-like drugs have been widely studied. After 3 years of extensive clinical investigation, certain facts pertaining to their use are generally recognized. The drugs are rapidly absorbed from the gastrointestinal tract, and repeated small doses maintain satisfactory blood concentrations. They enter most of the body fluids and tissues, particularly the thyroid, the blood, the bone marrow and the leucocytes. Transfer across the placenta also occurs and their goitrogenic action has been demonstrated in the fetal thyroid. Drugs of this type appear to be metabolized in the liver and excreted in the urine.

The thiouracil like drugs block the formation of thyroid hormone yet the exact mechanism by which this is accomplished remains obscure. The diminution of thyroid hormone formation with the ensuing drop in the blood concentration stimulates the anterior pituitary lobe to produce more T.S.H. which in turn induces further hyperplasia of the thyroid cells. Moreover the thyroid gland of the organism treated with the thiouracil like drugs is unable to respond to the usual pituitary stimulation. A drop in the basal metabolism consequently ensues. Approximately 1 day of medication is required for each percental elevation of the basal metabolic rate of the hyperthyroid patient. Depression of thyroid function to mixedematous levels may occur. The blood cholesterol, creatinine, and proteins return to normal levels as the metabolism decreases toward normal limits. These goitrogenic drugs further deplete the hyperthyroid organism of iodine which is excreted largely in the urine.

The effects of the thiouracil derivatives on exophthalmos are controversial but an increase in exophthalmos can and does occur during therapy as exemplified by one of our patients. Caution is advised when patients with severe exophthalmos are considered for such therapy. Enlargement of the thyroid and an increase in vascularity occur during therapy with the thiouracil derivatives. This becomes of significance in nodular goiters which may also present hemorrhage or malignancy.

Iodine medication following thiouracil treatment has been successfully used to decrease the hyper vascularity of the glands of patients prepared for surgery with the goitrogens. It has been reported that the operative and postoperative courses of patients prepared with thiouracil are much more quiet than those of patients prepared in the usual way. It has also been reported that the need for a stage thyroidectomy has been greatly decreased by the use of thiouracil preoperatively.

CONCLUSIONS

After an extensive survey of the experimental as well as of the clinical literature including a study of the findings of the patients in our clinic, the following conclusions pertaining to the use of the thiouracil like drugs seem reasonably warranted.

1 The drugs are capable of causing severe toxic symptoms and should not be used unless accurate observations can be made frequently preferably under hospital conditions.

2 The incidence of leucocytic depression is higher than is generally recognized since the criteria used have varied. In the majority of cases careful bone marrow studies have not been made.

The depression of the circulating leucocytes has thus far been interpreted to be due to depression of the bone marrow elements responsible for their production rather than to any effect (as yet undemonstrated) upon the mature leucocytes per se. The development of agranulocytosis is detectable in the bone marrow hours before it is shown by a drop in the circulating leucocytes and similarly the decrease in circulating leucocytes will occur before clinical symptoms develop.

3 Toxic reactions also occur during the treatment of hyperthyroid patients with propyl thiouracil.

4 The presence of nodular goiter should make one hesitant regarding the employment of thiouracil like drugs.

5 The drugs appear to be contraindicated by the following

a Hypersensitivity

- (1) Previous history of multiple allergies to foods, drugs (27, 166) and to foreign proteins
- (2) Previous history of sensitivity to the sulfonamide drugs (27). Simultaneous sulfonamide therapy appears inadvisable
- (3) Previous history of toxic reaction to one of the thiouracil-like drugs

b Bone marrow conditions

- (1) Pre-existing low initial white counts. This would be a contra indication since the patients would appear to possess less reserve if the drug were to depress the granulocytes.
- (2) Pre-existing blood dyscrasias due to bone marrow hypoplasia
- (3) The presence of an infection demands that the leucocyte response be optimal, and few will risk the unpredictable development of agranulocytosis in such cases (27, 32, 34)

c Exophthalmos, if severe, appears to contraindicate the use of the drugs (27, 34)

d Adolescence long continued treatment does not appear advisable at this time

e Toxic nodular goiter long continued treatment is inadvisable if this condition exists. The threat of malignancy developing in such goiters is well recognized. The functioning fetal adenoma falls into the same category (50, 128, 174)

- f. Pre-existing liver disease
- g. Pre-existing adrenal disease. The work of Baumann and Marine (15-16) suggests that thiouracil might cause additional tissue damage.
- h. Pre-existing renal disease, particularly if the renal sufficiency is questioned (166)
- i. Pregnancy. Carefully controlled studies on the experimental animal and in man are not yet available to judge the effects of such long continued therapy accurately on either the mother or the fetus. Widespread use of the drug during the period of gestation should be avoided until further studies are available unless the emergency is dire (17-34)
- j. Large cervical goiter (17) retrosternal goiter (206) retrosternal and retrovascular goiter and retrovisceral goiter as pressure symptoms may result in these conditions.

6. Indications for the use of the drugs appear to be found within that group of patients in whom the risk of thiouracil therapy is less than the risk of the disease when other methods of control are used. *i.e.* patients presenting

- a. Refractoriness to iodine (34)
- b. Hypersensitivity to iodine (185)
- c. Recurrent hyperthyroidism after previous thyroidectomy (34 151 187 195)
- d. Recurrent hyperthyroidism with hypertension.
- e. Ordinarily bad risks (21 23 56 116 117) (for preoperative preparation)
 - (1) Thyrocardias (115)
 - (2) Thyrotoxicosis (187)
- f. Hyperthyroidism, and patients who for one reason or another cannot have surgery

The use of thiouracil alone in the long continued management of hyperthyroidism is now severely questioned. Poate writes that "Early reports have given too optimistic an impression as to the value of the thio drugs. The history of thiouracil is already unpleasantly overloaded with claims for success which have had to be modified subsequently on account of toxic manifestations. McCullagh and his associates (140) state that the "risk of the drug (thiouracil) superimposed on the risk of the disease exceeds the mortality rate with treatment with iodine and competent surgery." Surgery (22) appears to remain the treatment of choice in the management of the majority of patients with hyperthyroidism.

Our own experience further emphasizes the advantages of the well established preoperative management of patients with hyperthyroidism. This consists of sufficient rest, adequate sedation, a high caloric, high vitamin diet, calcium, phosphorus, and vitamin D and iodination. This customary regimen reduces the period of preoperative therapy and hospitalization to a minimum. Moreover it eliminates the time expense, and technical assistance necessary for repeated leucocyte counts. The hypermetabolism resultant to the hyperthyroidism is sufficiently controlled in the great majority of patients without superimposing the risk of the thio drugs upon the risk of the disease, in order to permit adequate surgery. Since 1943, when thiouracil was introduced, 335 patients have been prepared for surgery in our clinic in the manner briefly outlined with a subsequent operative mortality of 0.29 per cent.

Remissions subsequent to adequate thyroidectomy are more certain and longer lasting than are those yet secured by treatment with the thioacil like drugs. It is our opinion that the now well established preoperative management of patients with hyperthyroidism followed by competent surgery will remain the treatment of choice until an antithyroid drug which will have a risk less than that of the disease itself is synthesized. Surgery thus remains the treatment of choice in the management of the great majority of patients with hyperthyroidism.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Cavernous Sinus Thrombosis. Samuel L. Fox and G. Brooks West, Jr. *J Am. M. Ass.* 1947 134 1452.

The term 'cavernous sinus thrombosis' is used to include phlebitis, thrombophlebitis and phlebotrombosis, as well as true aseptic thrombosis. By far the majority of reported cases are of septic origin and would therefore be classified as phlebitic or thrombophlebitic. Aseptic thrombosis and phlebotrombosis are usually secondary to trauma, a falling circulation, or to other noninfectious inflammation of the cavernous sinuses. Although thrombosis of the cavernous sinus is usually unilateral in its clinical manifestations, there is almost always bilateral involvement histopathologically because of the anatomic communications between the two cavernous sinuses by way of the anterior and posterior basilar sinuses, situated on the floor of the sella turcica under the pituitary body.

There are two primary types of thrombosis of the cavernous sinuses: septic thrombosis and aseptic thrombosis. The septic type of thrombosis is by far the commonest is of infectious origin and is secondary to a focus elsewhere. The onset is usually manifested by a severe chill, a high temperature ranging from 102 to 105 degrees F, extreme toxicity and perhaps nausea and vomiting. There is headache, but the patient is mentally alert until meningitis involvement occurs. The first localizing sign is definite edema of the bulbar conjunctiva and chemosis of the eyelids with rapidly progressive exophthalmos of the eye on the affected side, usually becoming bilateral unless the disease is arrested or the patient dies. There is also limitation of movement of the eye (abducens or sixth nerve paralysis) with concomitant alterations in sizes of the two pupils. Meningitis usually occurs rather early after which the sensorium is decidedly affected.

The two commonest conditions which must be differentiated from thrombosis of the cavernous sinuses are orbital cellulitis and lateral sinus thrombosis.

Prior to the introduction of the sulfonamide drugs as therapeutic agents, the treatment of thrombosis of the cavernous sinus was most unsatisfactory and the prognosis was extremely grave whether medical management or surgical intervention was employed.

The prognosis is still grave in spite of advances in the use of chemotherapy, anticoagulants, and antibiotic agents. The treatment of thrombosis of the cavernous sinus is purely medical, and surgical intervention is only indicated at the site of origin of the infection to eradicate the focus. The combined

use of sulfonamide compounds, antibiotics (penicillin, streptomycin and others) and anticoagulants in large doses is strongly advised. If the case is unresponsive to one of the sulfonamide drugs another should be substituted and the same is probably true of the antibiotic agents. The early employment of heparin and dicumarol administered simultaneously also is advocated.

Three cases of cavernous sinus thrombosis are reported (a with unilateral involvement and two with bilateral involvement) with two recoveries. In the first case the condition was unilateral and was thought to have followed adenotomyllectomy. In the second case the condition followed dental extraction with probable secondary sinusitis, and was complicated by meningitis. In the third case it was believed to have occurred following a gumma of the nasal septum with secondary infection in a person with uncontrolled diabetes.

EYE

Specific Treatment of Ocular Burns Due to Lewisite (3-Chlorovinyl-dichloroarsine). Irving H. Leopold and Francis Heed Adler. *Arch. Ophth., Chic.* 1947 38 174.

The authors present information on the specific treatment of ocular burns resulting from lewisite (3-chlorovinyl-dichloroarsine). An effective antisereneal agent, BAL (a 3-dimercaptopropanol) was discovered and developed during the war years which also proved effective against various types of arsenical poisonings in civilian practice.

The value of BAL for the treatment of burns of the eye is summarized as follows:

BAL is superior to hydrogen peroxide and potassium permanganate, which were previously used as therapeutic agents for this condition.

The longer the interval before the application of BAL to an eye burned by lewisite the lower the effectiveness of the treatment. The effectiveness decreases rapidly after from 10 to 12 minutes, but some effect is still present even after 30 minutes. The use of BAL an hour after contamination has no beneficial effect.

Better therapeutic results are obtained by reapplying the drug after the initial application.

Although unstable, watery solutions yielded the best therapeutic results. More stable solutions can be made with ethylene glycol or propylene glycol. These solutions retain full therapeutic efficiency for considerable periods of time under temperatures and exposures to air most likely to be encountered in practice.

Although preservatives do not reduce the therapeutic efficiency of BAL there is no necessity for their employment.

BAL also has been found to be therapeutically effective in ointment bases.

Several drops of 3 and 5 per cent solutions of BAL are just as effective as those of a 10 per cent solution.

BAL has a specific effect not only on ocular lesions resulting from lewisite but also on those from methyl dichloroarsene, ethyldichloroarsenine and phenyldichloroarsine and when used immediately after contamination of the eyes it has a beneficial effect on lesions due to mustard gas.

JOSHUA ZUCKERMAN M.D.

Penetration of Locally Applied BAL into the Anterior Chamber of the Rabbit Eye. Irving H. Leopold and Willard H. Steele. *Arch Ophth.*, Chic. 1947 38 192

The authors discuss the penetrability of BAL into the anterior chamber of the rabbit's eye. They conclude that after local application solutions of BAL in water and in ethylene glycol penetrate through the cornea into the anterior chamber. Penetration from a water vehicle is more rapid than that from an ethylene glycol vehicle. However aqueous solutions of BAL are unstable.

BAL penetrates more readily from a water containing base (K Y Jelly) than from a nonaqueous base (Friedenwald Fuqua ointment).

Greater penetration into the aqueous humor occurs from application of a 5 per cent solution of BAL in water than from application of a 5 per cent solution in ethylene glycol.

JOSHUA ZUCKERMAN M.D.

Gonorrheal Iritis: Experimental Production in the Rabbit. Maurice J. Drell, C. Phillip Miller and Marjorie Bohnhoff. *Arch Ophth.*, Chic. 1947 38: 221

Experimental iritis was produced in the eyes of rabbits, preferably albinos, by the injection of 0.2 c.c. of a saline suspension of two strains of gonococci into the anterior chamber with withdrawal of a like amount of aqueous. That it was a true infection was manifested by the multiplication of organisms and their recovery on culture. Inoculation with various numbers of organisms indicated 200 organisms to be the minimal infecting dose. The appearance of the experimental infection was similar to that frequently seen in such cases in the human eye. There was a gelatinous exudate, intense engorgement of the iris, and hypopyon and hyphemia. The infection remained localized in the anterior part of the eye.

The percentage of eyes yielding cultures containing the gonococcus fell progressively during the first week after inoculation. Injury to the lens at the time of the inoculation had a tendency to seemed to make the infection chronic.

In vivo testing of gonococcal agents was carried out. Details of this work are not related in the present paper, however, it is mentioned that although huge doses of penicillin systematically administered

were necessary to control the infection, as little as 2.5 units of penicillin injected directly into the anterior chamber were efficacious.

It is noted that an exact diagnosis of gonorrheal iritis can rarely be made in man. Paracentesis of the anterior chamber is not ordinarily feasible. Further more it was found that aspiration of aqueous frequently yielded no culture whereas postmortem culture of the tissues sometimes revealed a heavy growth of the organisms. The present knowledge of the immunological reactions in gonorrhea is not extremely helpful in establishing it as the etiologic factor in cases of acute iritis and the diagnosis of gonorrheal iritis must usually be presumptive.

WILLIAM A. MANN M.D.

Central Proliferant (Discol) Cataract and Its Hereditary Transmission. Andrew Rados. *Arch Ophth.*, Chic. 1947 38 57

The author analyzes a hereditary form of cataract variously known as Coppock's cataract (from the name of the family in whom it was first extensively reported), discol cataract (Doyle) or central proliferant cataract (Vogt) on the basis of a study of the family trees of patients whose cases have been reported. It is believed that the mode of inheritance is dominant. Evidence is presented to refute the idea of the recessive nature of the inheritance.

WILLIAM A. MANN M.D.

Substitution of Spinal Fluid for Vitreous. Milo H. Fritz. *Am J Ophth.*, 1947 30 970.

The author presents an historical account in which he describes the previous attempts to clear vitreous opacities by the substitution of normal saline and vitreous for the clouded vitreous. Following the suggestion of Hegner, who in 1929 used cerebrospinal fluid for this purpose, the author reports 4 cases in which cerebrospinal fluid was substituted for vitreous.

In only one case was the effort highly successful. A 13 year-old boy whose vision was reduced to light perception as a result of a traumatic hemorrhage showed a visual acuity of 20/20-1 in a period of 1 year after the procedure. Since the surgery was not performed until 12 months after the injury, it is unlikely that spontaneous improvement would have occurred. The other 3 patients, all of whom were in the late fifties, tolerated the procedure but did not obtain a satisfactory improvement in vision. This may have been due in one case to a previous retinal detachment and in the other cases to retinal damage from retinitis proliferans following repeated spontaneous hemorrhages.

The method followed was to perform a spinal tap on the patient in bed, transferring the sterile cerebrospinal fluid (4 c.c.) to the operating room. A quadrant of sclera was then exposed by making a conjunctival flap and a purse-string suture was placed at the puncture site about 12 mm. from the limbus. An 18 gauge needle is plunged into the vitreous and as much cloudy vitreous is extracted as can be

readily obtained, this usually being 1 to 1½ c.c. The globe collapses but assumes its normal condition when a similar amount of cerebrospinal fluid is injected. Examination with the ophthalmoscope in the successful case showed an immediate clear channel from the posterior lens capsule to the posterior pole, which enlarged subsequently.

This field in which there is at present much interest, may in the future offer some hope in other wise desperate cases. WILLIAM A. MAJOR, M.D.

EAR

A Study of the Eustachian Tubes and Their Orifices and Lumens in Patients with Large Operative Defects Giving Direct Visualization. Further Studies of the Muscles of Phonation and Deglutition. W. Likaty Simpson and Jones E. Witcher. *Ann. Otol. Rhinol.* 947 56 357

Studies were made by direct visualization of the palate, nasopharynx, and regions of the eustachian tubes in 5 patients with large operative defects. The movements of the soft palate, uvula, eustachian tube and lateral walls of the pharynx in pronouncing the vowels and consonants are the same except for degree. The soft palate and uvula are drawn upward. The lateral walls of the pharynx are drawn upward backward, and toward the midline. The eustachian tube mouth is drawn backward and downward, but there is no tendency for the tubes to close. Yawning produces a similar prolonged movement of these parts. In swallowing there is first a minor movement of elevation of the soft palate and medial displacement of the pharyngeal wall, then a major movement consisting of an upward movement of the posterior one-third of the soft palate and uvula, and depression of the remainder of the palate, followed by an upward movement of the entire soft palate and lateral pharyngeal wall. There is hermetic closure of the nasopharynx from the hypopharynx during deglutition. The normal eustachian tube is open at all times and is not closed or occluded by voluntary movements. JOHN R. LINDRAY, M.D.

Chronic Purulent Otitis Media. At St. Cuthbert. *Arch. Otolaryng.* 947 45 37

The first point which the author makes is the wide spread incidence of chronic running ear. There are about 2,800,000 cases in the United States, and the author believes that the responsibility for cure in these cases rests solely with the otologists.

In the great majority of cases, chronic purulent otitis media is believed to be dependent upon chronic purulent sinusitis on the same side as the purulent media, and usually radical surgical drainage of the chronic purulent sinusitis will clear up the chronic purulent otitis media in a dramatic way and in a short time.

A detailed report is given of 5 cases, all with associated purulent sinus disease, in which operation was performed on the sinuses with resultant clearing of the chronic otitis.

In conclusion, the author states that (1) in the great majority of the cases the chronic purulent otitis media can be cleared up the perforation of the drum can be closed the function of hearing, and the health of the patient can be restored by surgical drainage of the purulent sinusitis (2) in those cases in which the mastoid process has become involved the drainage of the purulent sinusitis will greatly facilitate the measures taken to clear up the involvement of the mastoid process, (3) as long as the activating purulent sinusitis is left undrained local treatment will prove unavailing and time-consuming.

The manner in which chronic purulent otitis will clear up following surgical drainage in a suitable case is startling and dramatic.

JOHN F. DUFFY, M.D.

Fenestration of the Labyrinth. O. Popper. *J. Laryngol.* 946, 61 441

The author reports in some detail the transstympanic approach for fenestration of the labyrinth. He states that his greatest problem in carrying out this approach was not the instrumentation, but the question of illumination, stereoscopy and magnification.

The author states that the hazards in this work are very formidable but under control as long as the surgeon can see. Therefore he describes and discusses in some detail the headgear which he has designed to help supply the proper illumination and magnification of the operative field. Briefly it is a headgear with a strong light and lenses which both magnify and light the operative field, as well as giving stereoscopy. A diagram of the headgear is presented.

The author discusses the anesthetic that he uses in carrying out his operation and he does not believe that the type of anesthesia is as important as the anesthetist. He is not greatly in favor of local anesthetics, but prefers general anesthetics—any of the various types, as long as they are given by a competent anesthetist.

Before the beginning of the operation the patient's head is placed in proper position and the skin is prepared in the usual manner. His incision is marked out in a brilliant green—a line running vertically down for about an inch and a quarter immediately in front of the tragus from the incisura tragi to a point somewhat in front of the lobule. He then infiltrates the temporomandibular cleft with a solution of saline containing 6 to 8 minims of adrenalin (1 in 10,000) to the ounce. He uses a fine needle and the point is directed backward, so as to hug the lamina tragi during the whole injection. The incision is made along the marking, now somewhat distorted by the infection. From now onward the operation may be conveniently described as falling into eight stages, as follows:

1. Exposure of the tragal cartilage and the cartilage of the external auditory meatus. The anterior surface of the tragal cartilage is freed and, once this is achieved, it provides a point for insertion of the

closed blades of a medium sized Killian speculum. The blades are gently opened and the whole tragal cartilage is cleared in very short time. The whole of the latter is exposed down to its attachment to the edge of the tympanic plate. An incision along its edge is made and the periosteum carefully reflected. Then the closed Killian blades are placed between the periosteum and the denuded tympanic plate and gently separated. The tympanic plate should be exposed for just over a quarter of an inch.

2 Separation of the cartilage from the edge of the tympanic plate. The author finds that this is very easily done with the use of the Killian blades. Small slivers of broadish cartilage may remain on the edge and they are removed in Stage 3.

3 Removal of portion of the tympanic plate. A long-bladed retractor is used and the posterior blade engages the free edge of the cartilaginous meatus and flattens the latter out against the bony posterior wall. The anterior blade pushes forward the temporomandibular joint plus anterior tissues that are present. When this is done, the drum is clearly seen with its vital landmarks. The edge of the tympanic plate is nibbled down with a rongeur until the entire drum is exposed to view. The author uses a Renter's automatic mallet for this procedure.

4 Fashioning of the tympanomeatal flap and exposure of attic wall and middle-ear contents. An incision about half an inch from the drum down to bone is made sweeping around the remaining portion of the bony meatus. The skin is gently reflected from the meatus and by working all the way around the skin is folded over the drum, its peripheral surface facing the operator. The meatal skin and drum become continuous at the tympanic ring. The posterior segment of the latter is detached from the sulcus tympanicus so that the meatal skin plus the posterior half of the drum may be folded over the handle of the malleus. After this the superlative landmarks in the middle ear are revealed. The meatal skin plus the attached drum are gently tucked into the recess between the remaining portion of the tympanic plate and the anterior part of the drum. The greatest care must now be taken not to tear the tympanomeatal flap with the use of the burrs. The author believes that only diamond burrs should be used as they require less pressure and are far less damaging to soft tissues should the latter be accidentally touched.

5 Removal of attic wall and exposure of incus. The operator uses a cylindrical diamond burr of 1/4 mm. diameter. The object is to drill a hole right through the attic wall to reveal the continuation of the incus in the attic space. Through the drilled hole the incus can be seen and the edges of the hole are then enlarged until the attic wall has been taken down in all directions. The body of the incus, its short process attached in the antral region and its articulation with the head of the malleus anteriorly are now exposed. This is practically all the bone removal that has to be done and the author believes that this minimal destruction of bone is responsible

for his not having any cases of otorrhea postoperatively.

6 Removal of the incus and exposure of the dome of the vestibule and facial canal. The main attachments of the incus are severed and the incudomalleolar articulation is now broken and the incus very carefully removed care being taken not to injure the chorda tympani. When this is done the dome of the vestibule, the facial canal, and other important landmarks can be seen.

The author also mentions an alternative technique to expose the dome of the vestibule but he does so with hesitation and the discussion is not in detail. He hesitates to mention it because the surgeon is deprived of most of his valuable landmarks with his alternate technique. This technique involves stages 4, 5 and 6.

7 Enchondralization of the dome of the vestibule. The author uses a flat-ended or spherical headed diamond burr for this procedure and the entire dome is ground down flat to a level below the facial canal. Bone dust and debris are removed by suction irrigation every few seconds, using a solution of 100,000 units of penicillin in 20 c.c. of saline. The facial canal and all other structures are under direct vision of the operator and they should not be injured if sufficient care is taken. The author does not use the mobile cartilaginous stopple of Lempert as he believes that it is the size of the fistula more than anything else that keeps the fistula open.

8 Replacement of the tympanomeatal flap to cover the fistula. The field is carefully cleansed, and when this is done it is found that the drum falls back into its accustomed place without tension or torsion. The meatal portion of the tympanic flap is placed over the dome of the vestibule its peripheral surface closely adapted to the fenestration. Narrow ribbon gauze impregnated with vaseline and sulfanilamide is gently packed on top of it and into the meatal passage. The other end of the strip is pulled through the intact meatus from below.

The postoperative care is mentioned and the author states that his results have been good and that he has had very little vertigo and spontaneous nystagmus afterwards and what occurs usually disappears after the third day. His patients usually begin to hear much better immediately after operation even with the packing within the ear.

The author discusses a hypothesis to account for hearing improvement after fenestration in otosclerosis. He presents this hypothesis based on the premises that sound transmission occurs through the round window. He considers the tympanic membrane to have three main functions: (1) It is the most perfect receptor for sound (2) It assists by variations of tension to focus for sound (3) It protects the organ of Corti by (a) an immediate tympanostapedial reflex, and (b) by relaxation, curtailing, and dampening sound vibrations.

The author briefly mentions some of the treatments used previously for otosclerosis which were all without value. He believes that the fenestration

operation is the procedure of choice, that it will be found more successful as time goes on and that his manner of the transtympanic approach, in particular will gain acceptance and will be considered the best approach.

The article contains some very excellent colored plates of the different steps in the operation.

WILLIAM A. ARKROW, M.D.

Tumors Involving the Petrous Pyramid of the Temporal Bone. Bruce Proctor and J. R. Lindsay
Arch. Otolaryng. Chic. 1947 45 80.

The petrous portion of the temporal bone may be involved by tumors originating within the temporal bone by tumors arising from adjacent structures, and by tumors metastasizing from distant primary foci.

The origin and the pathologic characteristics of meningioma involving the temporal bone are discussed. A case of meningioma of the temporal bone complicated by acute labyrinthitis superimposed on chronic labyrinthitis produced by the tumor is presented.

A case of sarcoma of the temporal bone is presented and the pathologic characteristics of the tumor are pointed out. Occasionally a tumor of this type is confused with meningioma.

The salient features of diffuse sarcomatosis of the meninges are briefly discussed and illustrated. When sarcomatosis involves the eighth nerve it may be clinically confused with neurofibroma, acoustic neuroma, or meningioma. In the case of diffuse sarcomatosis presented in this report a small focus of otosclerosis was found in each labyrinthine capsule in addition to bilateral involvement of the eighth nerve.

Neoplasms originating in the pons e.g. gliomas, may extend into the internal auditory meatus and interfere with the functions of the seventh and eighth cranial nerves.

A case of bilateral neurofibromatosis of the eighth cranial nerve in which psammoma bodies were observed in both of the internal auditory meatuses is presented. Since these psammoma bodies are usually found associated with meningiomas, their presence in conjunction with neurofibromatosis suggests a possible closer relationship between meningiomas and neurofibromatosis than has previously been suspected.

One case of metastatic tumor of the temporal bone is presented. The bone marrow of the petrous is capable of filtering out tumor cells circulating in the blood stream and becoming a secondary focus for a new growth.

Tumors involving the petrous pyramid of the temporal bone are relatively uncommon, present a wide variety of types and produce such a multififormity of subjective and objective symptoms that it was advisable to report some of the more unusual cases observed at the University of Chicago.

¹Clinics where the temporal bones were obtained for histopathologic examination.

The following types of tumors have been among those reported as primary in the temporal bone: meningioma, sarcoma, squamous cell carcinoma, plasma cell myeloma, hemangioma, epidermoid, dermoid, malignant melanoma, cylinder cell epithelioma and adenocarcinoma. JOHN F. DILLON, M.D.

NOSE AND SINUSES

Malignant Melanoma of the Nasal Mucosa. Charles C. Grace. *Arch. Otolaryng. Chic.* 1947 45 195.

Through the years, the question of the source of malignant melanoma of the nasal mucosa has been a matter of controversy. Wilkinson presenting the earliest report in the British literature in 1912 remarked that it was then generally accepted that these tumors arise in certain cells, stellate or spindle in form, occurring in the skin and the choroid, and less frequently in the mucous membranes of the nose and the mouth.

In the opinion of Ewing, the melanoma is a pigmented tumor arising from a specific mesoblastic cell, the chromatophore or from tactile cells lying in the epidermis or from nerve cells in the dermis.

In the upper portion of the nasal cavity the epithelium of the olfactory mucosa is filled with an abundant supply of granular pigment. It would seem reasonable that this upper nasal mucosa with its wealth of pigment should offer a site as favorable for the development of a melanoma as the richly pigmented surfaces of other parts of the body. However this is not the case for these tumors arise in the mucosa that is without pigment, either in the septum or in the lateral wall, including the turbinate.

In 63 of the cases mentioned in the literature the initial site was given as the nasal cavity in 17 patients, the septum in 21, the inferior turbinate in 14, the middle turbinate in 4, the middle and inferior turbinates in 1 patient, the lateral wall in 4 patients, the floor of the nose in 1 patient, and the external ala in 1. In the case presented by the author the melanoma arose in the inferior turbinate.

Usually the first symptom is unilateral nasal blockage which is soon associated with recurrent epistaxis. Occasionally the hemorrhage is frequent and profuse. Pain is not often a symptom unless the tumor has grown to the extent that there is pressure, or unless there is blockage of a sinus. The discharge of a blackish or ink-black serous fluid is frequently present.

Although pigmentation is usually present in great degree, it is not an invariable criterion in the diagnosis of this lesion. The histologic picture without the assistance of melanin may have to be the guide. The dopa reaction is of value in these instances for it indicates those cells which are true melanoblasts containing the oxidase ferment capable of transforming the colorless chromogenic material in the blood into melanin.

As to treatment, radiotherapy seems to be generally unavailing. Irradiation in addition to surgical intervention was employed in the treatment of 18

patients (43 per cent of the 42 cases in which therapeutic measures were described in any detail) without appreciable benefit.

The slow growth of the primary tumor as compared with the rapid dissemination of the metastatic lesions is an important consideration in treatment. Simple removal of the tumor although apparently complete and followed by irradiation with radium or roentgen rays seems to be of no permanent benefit. Radical removal including a wide margin of normal tissue would appear however to offer a reasonable chance of cure. Often in a nasal operation such removal cannot be performed without resulting deformity and impairment of function but it should nevertheless be undertaken even though the lesion is small.

A case of malignant melanoma of the nasal mucosa occurring in a negro 8½ years of age is reported in detail.

JOHN F. DEXTER, M.D.

PHARYNX

Tracheotomy in Bulbar Poliomyelitis. Robert E. Priest, Lawrence R. Boles, and Neill F. Golts. *Ann Otol Rhinol* 1947 56 230

During 1946 1,830 patients with poliomyelitis were treated in Minneapolis. Approximately 400 were diagnosed as 'bulbar' cases. Tracheotomies were performed in 75 of these. Twenty nine of the tracheotomy patients survived. Of this group 17 lived because of tracheotomy, a probably lived because of tracheotomy and 10 recovered after tracheotomy was done prophylactically.

Indications for tracheotomy included (1) respiratory distress as evidenced by recurrent cyanosis, coarse rales in the chest and laryngeal stridor, (2) unmanageability causing the patient to resist pharyngeal aspiration, (3) stupor of sufficient degree to make the patient oblivious of secretion in his airway, (4) inability to cough effectively, (5) pharyngeal pooling of mucus, (6) vocal cord paralysis and (7) intralaryngeal hyposthenia as demonstrated by laryngoscopy.

Cyanosis can be diagnosed clinically only when anoxia is far advanced and irreversible damage has already occurred to already diseased neural tissue. Tracheotomy should be performed before anoxia has produced damage of the nervous system. Aspiration, bronchitis and pneumonitis, anoxia, and fatigue are minimized by keeping the airway clear. In 15 cases gross amounts of pharyngeal secretion or food or both were aspirated from the trachea at the time of surgery. Immediate relief from anoxia resulted with general improvement in the condition of the patient. No deaths were attributed to tracheotomy. Intermittent pharyngeal aspiration by nasal catheter was found to be superior to continuous suction. All patients have been decannulated but 1 adult who became physiologically dependent on her tube and 1 child who had a residual laryngeal paralysis. Tracheotomy in conjunction with artificial respiration will enable some critically ill poliomyelitis patients to

survive until natural recovery of damaged neural tissue can occur. Seventeen case histories are presented.

JOHN R. LINDSAY, M.D.

NECK

Intratracheal Gopher. Lara, Thorén; *Acta chir scand.*, 1947 95 495

The author reports a case of intratracheal gopher resulting in fatality because of stenotic symptoms. The patient was a woman, age 30 who had a prominent gopher dating from about the time of puberty. For a period of about 5 years she had experienced respiratory difficulties, which were aggravated premenstrually and in connection with two pregnancies. A probable diagnosis of intratracheal gopher was made on the basis of the history, clinical study, laryngoscopy and roentgenograms. Because of the pronounced stenosis preparation was made for operation, but the patient died from suffocation although intubation and other aids were performed. The suffocation may possibly have been due to some great extent to a reactive swelling and hyperemia after treatment with vascular constricting agents used in laryngoscopy. At autopsy and on microscopic examination direct connections were found between the intratracheal gopher and the retrotracheal portion of the outer gopher via the cricotracheal membrane. The increase in size of the intratracheal portion in connection with the pregnancy and an adjacent acute laryngitis were probably decisive in the unfortunate outcome. There were no symptoms of thyrotoxicosis.

There are several theories regarding the genesis of intratracheal gopher. In some cases it most probably occurs on the basis of a total or partial detachment of parts of the thyroid glandular primordium (von Brun, Hultén). In other cases the source might be explained in accordance with the ingrowth theory (Palttauf, Wegelin) which is supported by Wegelin's investigations. The present case can be elucidated both by the ingrowth theory and that of Hultén.

Cases of slight intratracheal gopher may run their course without any appreciable symptoms. When symptoms occur the picture of the disease is dominated by stenosis in the upper air passages which is usually slowly progressive. The first appearance of symptoms often occurs at puberty and exacerbations are prone to occur premenstrually and in connection with pregnancy. At laryngoscopy particular attention should be paid to the region below the vocal cords where the intratracheal gopher takes the form of a rounded even curvature inwards in the subglottic space. The roentgen picture may be typical in some cases and of value in differentiating the lesion from an extratracheal gopher. If stenotic symptoms persist or recur after thyroidectomy for extratracheal gopher in patients in whom these symptoms have been prominent one should suspect intratracheal gopher.

The treatment of the condition is operative. A simultaneous pregnancy constitutes no contraindication.

cation to operation but increases the indication. The intratracheal goiter is extirpated pertracheally or by laryngofissure. Recurrence is seldom encountered. The mortality of operation becomes high when extirpation is performed late and under unfavorable circumstances.

JOHN L. LUNDQVIST, M.D.

Thyrototoxic Crisis. Janet W. McArthur, Rufon W. Rawson, J. H. Means, and Oliver Cope. *J. Am. M. Ass.* 1947 134 868.

This report is on 25 surgical crises and 11 medical crises which occurred among a total of 2,033 cases of thyrotoxicosis during 25 years. Twenty-five of these surgical crises followed 1,383 operations and 11 medical crises followed some precipitating cause. Sixteen of the surgical and 8 of the medical cases terminated fatally. The season of the year exerted but little influence on the frequency of the thyroid crises. The average age of the patients experiencing surgical crises was 46 years. The average age of those experiencing medical crises was 39.4 years. Ten of the 11 medical crises and 17 of the surgical crises occurred in women. Thus a 1 to 3 ratio of males to females experiencing crises occurred. Eight of the medical and 12 of the surgical crises occurred in patients with diffuse goiter. Three of the medical and 13 of the surgical crises occurred in patients with toxic nodular goiter. The relative toxicity of the 2 types of goiter and the mortality rates almost coincided. The majority of crises occurred in patients with thyrotoxicosis of short duration.

A table is presented which summarizes the amount of weight lost between the time of onset and the time of admission to the hospital. Eleven tables are presented in detail which show summary of the data, the age incidence of thyroid crises, the duration of symptoms of thyrotoxicosis, the amount of weight loss, the basal metabolic rate on admission, the therapy prior to hospital admission, the incidence of complicating disease, the pathologic findings in autopsies of 12 patients who died of thyroid crises, the influence of age and complicating diseases on survival, the precipitating factors in the development of thyroid crises, and the factors influencing survival from surgical thyroid crises.

Severe complicating diseases, especially heart disease, were common in thyrotoxic patients in whom a crisis developed and exerted a significant influence on the survival of such patients. Postmortem findings showed that few patients had any demonstrable hepatic lesions but disclosed the frequent occurrence of cardiac and pulmonary pathologic conditions.

The precipitating factors which appeared to be provocative of crises were thyroidectomy (14 cases), pneumonia (7 cases), iodine withdrawal (4 cases), postoperative hemorrhage and secondary anuria (3 cases), wound sepsis (1 case), and digitalis intoxication (1 case). Patients who failed to gain weight and whose symptoms were not improved preoperatively did not survive thyroid crises.

Three case histories are discussed in detail and it is suggested that in every case of thyroid crisis

therapy should be individualized to correct all the abnormalities. It is necessary to continue the administration of antithyroid drugs until the patient is in a suitable condition for surgery.

RICHARD J. BERNETT, JR., M.D.

Carcinoma of the Thyroid. Robert C. Horn, Jr., Robert F. Welty, Frank P. Brooks, Jonathan E. Rhoads, and Eugene P. Pendergram. *Ann. Surg.* 1947 126: 140.

Although most thyroid cancer occurs in nodular goiters, the incidence of malignant tumors in nodular goiters has been regarded by many physicians as too low to be accepted as a valid indication for their routine removal. However as the operative risk has declined, it has become probable that life can be saved by taking a more radical attitude toward nodular goiters. The use of postoperative radiotherapy has been a moot point and it is with a view to clarifying this subject that the authors have reviewed all of the cases observed at the Hospital of the University of Pennsylvania, Philadelphia, for as 11 1/2 year period.

Seventy-one patients with carcinoma of the thyroid and 3 patients with lateral thyroid carcinoma were treated during this period. Sixty-two cancers of the thyroid were encountered among a series of 2,070 surgically treated patients with thyroid lesions, an incidence of 3.0 per cent. Among 2,135 surgically treated nodular goiters the incidence of carcinoma was 5.5 per cent.

Thyroid carcinomas occurring in the younger age groups tend to be the less malignant of the pathologic types of the condition and are less advanced in their growth when they first come under observation. Seventy per cent of the carcinomas in the authors' series occurred in patients between the ages of 40 and 70 years, and 76 per cent of the growths occurred in women.

The majority of thyroid carcinomas are of the papillary or malignant adenoma types, and these may be grouped together as grade I tumors, i.e., tumors of low grade malignancy. Fifty-eight per cent of patients treated for tumors of this type survived for a period of more than 5 years, and 60 per cent of the patients treated longer than 1 year ago are alive and well. Although the prognosis in tumors of other pathological types is poor, the 10 year survivals in the authors' series include 1 patient with a small cell carcinoma and 1 patient with a giant cell sarcoma.

The extent of the disease at the time treatment is instituted is more important prognostically than its pathological type. Eighty-six per cent of the patients whose tumors were discovered only on pathological examination and who were treated more than 5 years ago, are alive and well. Seventy-five per cent of such patients treated more than 10 years ago are alive and well.

Many patients with thyroid cancer develop metastases or recurrences 5 years or more after their initial treatment. This series includes 1 patient who

died with metastasis more than 10 years after thyroidectomy

In view of the relatively small risk of operation it would appear wise to recommend the surgical excision of all nodular goiters unless strong contraindications exist. The extension of carcinoma through the capsule of the gland indicates the institution of postoperative irradiation. It has been especially effective in the papillary carcinomas. The benefits of postoperative irradiation in cases in which the carcinoma has not extended through the capsule are not clear from the present study. So many of these patients do well that a considerably greater experience will be required before postoperative irradiation in this group of cases can be finally evaluated.

ERNEST D. BLOOMENTHAL, M.D.

Aberrant Papilliferous Cervical Tumors (Tumores papilliferos cervicales aberrantes. Parte anatomoclinica) A. Bianchi *Arch. cubanas cancerol.* 1947 6 117

Aberrant thyroid tissue may give rise to cervical tumors which can be found isolated in lymph glands or other associated lymphoid tissue. Because of the slow growth of these tumors and their malignant appearance they are frequently mistaken for a malignant process although a papilliferous structure may be found both in carcinomatous or noncarcinomatous tumors.

To overcome this difficulty of differentiation one must carefully study the histological appearance of the cells that cover the papillae, capsulation of the tumor and, lastly, invasion of the blood vessels. Some papilliferous structures in the lymph glands have their origin from malformed pharyngeal tissue, as in the latter epithelial and lymphoid tissues are side by side in the embryo. A fibrous capsule between the papilliferous process and the lymphoid or thyroid tissue is of diagnostic value as it indicates whether one is dealing with a malformation or a metastatic process.

ARTHUR F. CIPOLLA, M.D.

Nature and Characteristic Features of Laterocervical Branchiogenic Carcinoma (Natura e caratteristiche dei carcinomi branchiogeni laterocervicali) Federico Pizzetti *Tumori Milano* 1947 33 25

Some writers deny the existence of laterocervical branchiogenic carcinoma but the author advances valid arguments in favor of such a clinical entity. He bases his opinion on personal observations and clinical, embryologic, and anatomopathologic data. The generic term 'branchiogenic tumor' branchioma, or cervical embryoma is frequently applied to a variety of tumors.

The following conditions should be taken into consideration in the differential diagnosis: various types of carotid paragangliomas, lymphoepithelioma, rare epitheliomas deriving from an ectopic inclusion of salivary gland in cervical lymph glands, carcinoma of the thyroglossal duct, certain forms of pseudocarcinomatous mixed tumors of the salivary glands and various types of connectivoma.

Two types of tumors originating from the branchial cleft may be distinguished: (1) benign, represented by branchial cysts and encapsulated adenolymphomas and (2) malignant, represented by branchiogenic carcinomas in the strict sense of the word.

Among 100 cases of lateral tumors of the neck observed by the author, he found 11 in which the diagnosis of laterocervical branchiogenic carcinoma could be established. Only 3 patients were younger than 40 years. The tumors were located in the mesenchymal area and showed a relatively rapid growth. They were of hard consistency and showed a tendency to adhere to the skin only in advanced stages. Secondary ulceration of the skin occurred in several instances. Metastases were found in the liver, bones, lungs and regional lymph glands. The pharynx was secondarily invaded in 1 patient.

The autopsy revealed a typical macroscopic aspect of carcinoma with occasional necrotic or pseudocystic areas. The histologic examination established the presence of structures of ectodermic and entodermic origin.

JOSEPH K. NAKAT, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Isolated Oculomotor Palsy Caused by Intracranial Aneurysm. Geoffrey Jefferson *Proc. R. Soc. M. Lond.*, 1947 40 2 9.

In order to study each aspect or type of symptom found in cerebral aneurysms, the author discusses the occurrence of an isolated oculomotor paralysis as the essential feature. Fifty five aneurysms out of a total of 158 had this isolated paralysis. Although it is agreed that the majority of patients had congenital aneurysms it is believed that they probably developed later in life from congenital defects and in a sense, may be compared to inguinal hernias appearing in later life.

The most common site is the distal portion of the internal carotid artery soon after entering the intracranial cavity by piercing the dura mater and hence is supraclinoid in position. The posterior communicating artery may be either above or below the aneurysm. The constant features are that the aneurysm has a pear-shaped configuration and faces posteriorly. The aneurysm occurred on the basilar artery in only 3 of a total of 55 cases.

All portions of the oculomotor nerve are not equally involved. Although ptosis is the most common finding many patients will note diplopia before the ptosis. The patients often stated that the eyelid felt heavy and that this with the pain, caused them to close the eye although after several days to a week they may awaken to find they are unable to open the eye. The pupil is at first classically dilated but usually within 2 to 4 weeks may contract slightly. Recovery starts in several weeks regardless of whether the carotid is ligated or not. This is almost never complete, the least recovery occurring in the superior rectus muscle.

Pain is a very characteristic and distinguishing symptom. It is always in the ophthalmic division of the trigeminal nerve ipsilateral forehead and about the inner canthus of the affected eye. When associated with severe occipital headache and nuchal rigidity it is indicative of subarachnoid hemorrhage. Anesthesia is not usually present but if it is the aneurysm is subclinoid.

Subarachnoid hemorrhage occurred in 30 patients, or 70 per cent of the cases. Although it was fatal in 7 cases, while the patients were in the hospital it is surprising to note that nearly all immediate survivors are still alive.

Arteriosclerotic aneurysms were present in 10 per cent of the patients about a third of whom were hypertensives. An important finding is that hypertension in the older age group is not an absolute contraindication to carotid ligation since 2 patients 57 and 56 years of age had internal carotid and common carotid ligations, respectively and were alive

and apparently without ligation sequelae after 2 years in 1 case and after 6 months in the other. As might be expected many of these patients are poor risks and do not warrant surgery, death usually resulting from angina or myocardial failure.

The differential diagnosis is seldom a particularly difficult problem. So-called ophthalmic migraine can be differentiated by a detailed and careful history revealing the absence of residuals. Carcinoma of the nasopharynx does not give an isolated third nerve palsy. Although the author encountered 3 pituitary adenomas with oculomotor paralysis, an associated visual field defect was found in all patients.

The surgical approach finally selected as the procedure of choice was ligation of the carotid trunk. In some cases the common carotid was ligated first and later the internal carotid however the results were as good in one as in the other. After a fatality from an attempt to clip the neck of an aneurysm intracranially, this procedure was discarded as too hazardous although intracranial carotid clipping, or ligation and trapping of the aneurysm is considered satisfactory. The former was performed in 23 cases. The operations on the 3 patients who died within a day or so were emergency ties, as the patients were semi comatose. One patient died 7 years later from an unknown cause hence 10 patients have survived. In 3 other cases an attempted ligation was abandoned due to hemiplegic signs.

The most important criteria in suggesting surgery is pain since it is felt that pain implies that some activity is occurring in or about the aneurysm.

The most astounding finding is that "few patients who remain pain-free come to any harm whether operated upon or not." JACK L. WOOLSEY M.D.

Neurinomas of the Cerebellopontile Recess. A Clinical Study of 164 Cases Including Operative Mortality and End Results. Antonio Gonzalez Revilla. *Bull. Johns Hopkins Hosp.*, 1947 80 254.

This study of neurinomas of the cerebellopontile recess was based on operations performed by Walter Dandy at The Johns Hopkins Hospital in the period from 1926 to 1945. There was a total of 160 cases, of which 145 were acoustic neurinomas, or those originating predominantly from the eighth nerve. There was an extreme variation in the ages of the various patients, ranging from 13 years of age to 69 years of age. The average age of the patients derived from the onset of symptoms was 39.6 years. The average age on admission to the hospital was 44.2 years hence there was an average duration of symptoms before surgery of 4.56 years.

Although the prominence of the elements varies in the symptomatology the various elements were, nevertheless present in most cases. Auditory and labyrinthine symptoms were present in every case.

They were noted as the initial symptom however in only 68.6 of the cases. Diminution of the auditory acuity was subjectively present in all cases despite the fact that there was no objective evidence of hearing loss in 5 cases. Tinnitus was present in 62.3 per cent of the cases. Cerebellar symptoms such as unsteadiness in walking, staggering, clumsiness were present in 86.2 per cent of the cases. Headaches were not as frequent as noted in earlier reports; however they were present in a little over two-thirds of the cases and were noted as the initial symptom in 12.4 per cent of the cases. The headaches were usually localized to the occipital region although at times they were quite variable extending from the suboccipital to the frontal region. Symptoms referable to the trigeminal nerve were found in 56.5 per cent. Numbness was usually the predominant sign although an occasional case suggestive of a typical tic douloureux was noted. Evidence of involvement of the facial nerve was present in only 15.8 per cent. The sparing of the facial nerve remained a surprising finding as has been noted in the past.

Audiograms were performed in all cases except 1. Some degree of impairment was noted in 95.8 per cent of the cases. This was found to be as follows: there was total deafness in 107 cases and partial in 32. Although 5 cases showed no abnormal changes in the audiogram it should be noted that these cases showed disturbances in vestibular function. The cold caloric test for vestibular function was not performed routinely. Among 87 cases however in which it was used there was a loss of caloric response in 66 cases and a partial disturbance in 11.

From these findings it was concluded that one would expect involvement in some portion of the eighth nerve in all cases of acoustic neuromas. It is disclaimed, however, that all acoustic neuromas arise from the vestibular portion of the nerve rather than the author believes that they may arise from either the vestibular or the auditory branch as has been proved by the work of Hardy and Crow.

The operative mortality rate has diminished with the evolution of newer approaches as advocated by Dandy with the natural improvement in technique which occurs over the passage of years. With the unilateral cerebellar approach and careful intracapsular dissection there was a mortality rate of only 6.5 per cent in patients operated upon in the last 8 years. The author reports the outstanding figure of only 2.4 per cent or 1 fatality in 41 patients who were operated upon in the past 5 years.

An analysis of the operative deaths reveals that neither age nor symptoms have any particular correlation with the cause of death since there was no greater predominance in either young or old patients nor any correlation with the severity of the symptoms. A surprising finding was a very definite increase in mortality rate in males. The average weight of the tumors removed was 27.6 gm. The greatest primary cause of death was direct trauma to the brain stem. Other factors were meningitis, pulmonary complications, and vascular complications.

Although the importance of preserving the facial nerve is well recognized and emphasized this could be done in only 9 cases. Needless to say it was felt that despite the great desire to save the facial nerve the possibility of adherent tumor capsule to the nerve made it necessary to sacrifice it in most cases. X ray evidence of destruction of the porus acusticus was present in only 50 per cent of the cases. Hence, the absence of x ray evidence of bone destruction of the acoustic canal should not hinder one in making the correct diagnosis.

The association of unilateral acoustic neuromas with peripheral neurofibromatosis was found to be very infrequent since only 5 cases with this association were found in a series of 160 cases of cerebello-pontine recess tumors. In studying this specific type of tumor it was noted that the age at the onset was definitely far below the age of patients with solitary neuromas that is the age group revealed an average age of 24.3 years. The average age at the onset of symptoms was only 14.3 years with a quite prolonged duration of symptoms (10 years). The symptomatology was very similar however to that of the type without acoustic neuromas. At the time of operation however it was noted that the neuromas were extremely hard, which made their removal by curettage a very difficult and extremely hazardous procedure. With the possibilities of other neuromas and the possibility of development of meningiomas the final outcome was very bad. In the present series of only 3 cases there was 1 operative death, 1 death 7 years later from recurrence and 1 patient living and well at the end of 6 years.

Bilateral acoustic neuromas were found in 6 cases representing 3.7 per cent. There was a rather definite relationship with von Recklinghausen's disease since 3 cases representing 50 per cent, showed definite evidence of peripheral neurofibromas. A more striking correlation was noted to be a hereditary transmission with familial predisposition. This was noted in half of the cases. The symptomatology was not a great deal different from that of other neurofibromas except that it was more similar to that of the cases of unilateral neuromas associated with von Recklinghausen's disease that is this condition usually occurred in definitely younger individuals the average age at onset being 17.8 years of age. The symptoms however, were usually of some what shorter duration probably because of the bilateral involvement. As would be expected the operative mortality of such tumors is definitely higher because of the difficulty of operating on 2 sides and the greater possibility of edema resulting from operation in a reduced space. Hence the best approach with extirpation of the tumor is a bilateral cerebellar approach.

Neuromas of the fifth nerve are comparatively rare comprising 3 cases of the present series. The symptomatology was very similar to that occurring in acoustic neuromas with the exception that trigeminal symptoms preceded auditory and labyrinthine disturbances by an average of 4½ years. In 3

of the patients the symptomatology was that of tic douloureux. There was no immediate operative mortality. However a careful follow up could not be obtained in any case. An interesting finding was that in 1 case there was a marked return of auditory function following operation.

Neurinomas of the tenth nerve occurred in only 3 cases. There was 1 very definite and predominant symptom found in both cases, and this was hoarseness which was the initial symptom in 1 of the cases. The remainder of the symptoms may at times represent quite a problem. However as a whole they might mimic any cerebellopontile tumor or an acoustic neuroma. There was no operative mortality in this group.

Only 1 case of neurinoma of the eleventh nerve was found, and in this case there was a very definite connection with the generalized neurofibromatosis.

JACK I. WOOD, M.D.

Penicillin in the Prevention of Infection during Operations on the Brain and Spinal Cord.
J. B. Pennybacker, Margaret Taylor and Sir Hugh Cairns. *Lancet* Lond. 1947 3: 59.

A study was made of the local use of calcium penicillin powder mixed with sulfamesathine in the prevention of infection of operative wounds in brain and spinal cord conditions. There were 5,000 units of penicillin per gram in the mixture. The powder was lightly insufflated onto the various layers of the wound including the surface of the brain and spinal cord. At 40 operations an average of 1.4 grams (7,000 units of penicillin) of powder was used. In a study of one series of 24 cases of tantalum cranioplasty and a second series of osteoplastic craniotomies, 10.3 grams of powder were used and it was found that penicillin was usually present in the wound in adequate bacteriostatic concentrations for 18 hours. The first 24 hours are the most important in prevention of the establishment of infection.

No convulsive seizures followed the application of this powder to the brain. In some laminectomy wounds where a large surface of muscle was exposed a slight excess of exudate was noted, and the wounds were drained through a small stab incision.

During the prepenicillin era from May 1938 to November 1944 there were 169 clean major cerebral and spinal operations performed at the authors' hospital. Among these, 51 cases were infected and in 13 cases the infection was fatal. From December 1944 to March, 1947 penicillin sulfamesathine powder was insufflated locally into 670 similar type wounds with the result that there were 6 wound infections with no fatalities from these complications. Thus the incidence of infection was cut from 4.4 per cent in the prepenicillin era to 0.9 per cent with local application of the penicillin-sulfamesathine powder.

The powder gives only slight assistance to the body in overcoming wound infection. It does not prevent virulent infections nor does it replace any of the measures used to combat infection at the operating table.

SPINAL CORD AND ITS COVERINGS

Peripheral Extension of Radiopaque Media from the Subarachnoid Space. J. Douglas French and William H. Strain. *Surgery* 1947 3: 380.

In a series of 300 consecutive myelograms, 4 cases were encountered in which pantopaque extended outside the normal confines of the subarachnoid space apparently along the nerve roots. A report of these 4 cases is presented. In one case a definite anatomic abnormality was demonstrated at operation. The second case was one of subarachnoid block just above the point of injection, and extension of the medium along the nerve root was thought to be due to anatomic changes which developed as a result of a chronically obstructed arachnoid space, as well as pressure alterations produced by the injection of additional fluid into a small closed space, and also probable injection directly into a nerve root rather than into the subarachnoid space. In the third case, the probabilities are that the material was injected outside the subarachnoid space. In the fourth patient, injection is thought to have been made presumably into the perineural spaces of the nerve root.

The author has conducted experimental work on rabbits and dogs, with injection of radiopaque media in the peripheral nerves and into the subarachnoid spaces of the spinal canal, under normal and increased pressure conditions. In another group, injections were made into the intracranial subarachnoid space under physiologic pressures.

Under normal pressures, it was found that the opaque materials made rather rapid exit from the intracranial spaces, through the cribriform plate, into the nasal secretions and cervical lymphatic system. Extension of radiopaque material from the lumbar region was never observed under physiologic conditions, but did occur into the perineural spaces when excessive pressures were applied or the animal was killed.

Peripheral injections of nerves indicated that there may be a connective tissue plane organized from the dural perineural sheath which form discrete channels in such a fashion as to subdivide the progressively branching nerve into longitudinal compartments supporting axis cylinder extension.

No evidence could be found to indicate that there is a physical communication normally between the spinal subarachnoid space and the peripheral nerves. Under unusual circumstances, such extension may occur along the nerve sheath from the subarachnoid space.

PERIPHERAL NERVES

Injuries of Peripheral Nerves in Two World Wars. W. Rowley Bristol. *Brit. J. Surg.* 1947 34: 333.

The author discusses the influence of Sir Robert Jones on surgery of the peripheral nerves, and gives a brief résumé of his work in this field.

A further discussion ensues with reference to developments in peripheral nerve surgery during World

War I including end to-end suture assessment of results from nerve graft (which was uniformly poor) and the conclusion that neurological recovery always fell short of perfection under the best operative conditions.

The use of splints to overcome and prevent deformity is outlined although it is also stressed that preserving joint mobility is essential. Physiotherapy was apparently used more in World War I than in World War II in the British Army.

The operative technique employed in World War II is outlined and includes wide anatomical exposure, alterations in position of the limb, stripping of branches transposition of nerves, bulk suture of the sheath with stainless steel wire and fine nonabsorbable thread is recommended. Protection of the suture line with nonabsorbable material proved unsatisfactory.

The problem of primary and secondary suture is discussed and ideas for and against these procedures are presented. It would appear to be evident that delayed suture (2 or 3 weeks after injury) may have some advantages in some series a greater percentage of success in delayed sutures is reported in contrast to primary sutures.

The author is inclined to believe that delayed suture is not advisable unless there is good reason to delay as in an open wound with potential infection which otherwise would be an end to-end suture. Neurolysis is not considered a very valuable procedure although the author has not clearly defined what he considers a neurolysis to be.

Composite tables have been set up to assess motor and sensory recovery. These include various degrees of sensory recovery and motor improvement a review of the tables permits a ready evaluation of a case or group of cases. Recovery in various nerves has been considered and the radial nerve again heads the list of recoveries. Recovery in median nerve in injuries follows. In injuries of the upper extremities recovery in the ulnar nerve was poorest. In the lower extremities medial popliteal sutures showed a fairly good degree of recovery while lateral popliteal results were poor.

Nerve grafting both heterogeneous and homogenous was considered a failure.

HOWARD A. BROWN, M.D.

Surgical Experiences with Peripheral Nerve Injuries.
Herbert J. Soddon. *O Bull. Northwest Univ. Med. School* 1947 11: 201.

About 2,500 cases of peripheral nerve wounds in military and civilian personnel were studied in England and Scotland at 5 centers devoted exclusively to treatment of this type of injury. The classification of types of peripheral nerve injury devised by Professor Henry Cohen was used namely neuropraxia, neurotmesis and axonotmesis. In neuropraxia there is no axonal degeneration and no change in the muscles supplied by the affected

nerve. The essential lesion is presumed to be due to fragmentation of the myelin sheath. Recovery is complete and rapid.

Neurotmesis is defined as an injury in which fibers of one kind may grow into tubes leading to end organs of another kind as a result the axon is wasted with subsequent imperfect innervation.

In axonotmesis the fibers may grow into a Schwann tube of the proper kind but leading to a destination different from the one originally served by that particular fiber. As a result there is a permanent impairment of a point discrimination sensibility weakness in individual muscles and imperfect participation in synergic movements.

In regeneration there is a progressive diminution in the rate of growth the process becoming slower as it approaches completion. Nevertheless the rate may be approximately constant over moderately long periods and in man is roughly from 1 to 1.5 millimeters per day. The decrease in rate of regeneration may be due to progressive shrinkage of the Schwann tubes in the peripheral stump after section of a nerve. As a result the growth in diameter and myelination are hindered and both of these are noted that there were noxious changes in the muscle itself and that progressive atrophy had a retarding effect on reinnervation and function. Atrophy of a denervated muscle is reversible up to a certain point. Its greatest effect is that of interstitial fibrous invasion. Schwann tubes where they approach their innervation. The proximal fiber is prevented from reaching its old motor end plate.

In general, primary nerve suture gives less satisfactory results than early secondary repair for the following reasons:

1. The extent of intraneural damage in a severed nerve cannot be adequately evaluated immediately and it is only after a few weeks of growth that fibrosis of the damaged zones becomes apparent.

2. Suture of the epineurium is always carried out rather than suture of the nerve itself. This structure is usually quite thin at the time of injury. After a short interval a certain degree of thickening occurs which permits a firmer suture of the epineurium and one that is more accurate in apposition.

Mobilization of the nerve stumps is essential to avoid tension at the suture line. In order to accomplish this it is necessary to expose larger areas of tissue with the risk of spread of infection.

A review of 1,681 cases during this period showed that 41.5 per cent required surgical repair. A breakdown of these figures is given. In considering nerve grafting it was believed that heterogeneous grafts were a failure, homogenous grafts were moderately good, and autogenous grafts were most successful. The factors involved in nerve grafting are discussed. In a series of 58 cases of autogenous grafts the degree of regeneration was sufficient to justify the procedure in more than 50 per cent of the cases. In general, the results were encouraging when the severity of these wounds is considered and the author no longer

regards autogenous nerve grafting to be merely an experimental procedure

RICHARD C. SCHÖNEMER, M.D.

An Operation for Nerve Pedicle Grafting. F. G. St. Clair Strange. *Brit. J. Surg.* 1947 34 423

The author reports a method of nerve grafting employed in one patient with injuries involving both the median and ulnar nerves in the forearm. No follow-up studies to indicate the result, are reported.

The author recommends the method in an attempt to improve the circulation to the graft, but it would require a situation in which two nerves were involved, and one must be sacrificed in an attempt to improve the second.

In this case, the proximal ends of the two nerves were identified and resected until satisfactory nerve bundles were found. These two nerves were then approximated, both being proximal segments.

At a second stage operation about 6 weeks later the ulnar nerve was freed at a considerably higher level than the point of suture of the two proximal ends and was then divided. The nerve was then swung downward and carried through a tunnel so that it could be approximated to the distal portion of the median nerve below.

The author believes that such a pedicle nerve autograft may have application in certain special situations of the type here described.

HOWARD A. BROWN, M.D.

Regeneration of Severed Nerves. Lewis J. Pollock, James G. Golsmith, Frank Mayfield, Alex J. Arieff and Others. *J. Am. M. Ass.* 1947 34 350.

The authors present evidence that regeneration of a distal segment of an injured nerve occurs in spite of separation of the segments. Proof of regeneration is seen when there is recovery of voluntary motion, recovery of sensation in the isolated supply of a nerve, histologic evidence of fibers in the distal segment, response of muscles to direct electrical stimulation of the nerve and reactions of muscles which show there is no complete denervation when they are stimulated electrically. A chronaxia of less than 15 milliseconds for response to faradic stimulation and a galvanic tetanus ratio of more than 1.0 satisfy the latter requirement. The galvanic tetanus ratio of a completely denervated muscle is 1.0. Since regeneration and degeneration proceed simultaneously there may be instances in which the galvanic tetanus ratio may never be found to be 1.0.

Eighty-four cases were selected for study. The ends of the nerves were separated by gaps up to 9 cm. in length. Only in 1 case did stimulation of the distal segment produce a response when it was studied at the time of the original operation.

At surgery very few instances of a galvanic tetanus ratio of 1.0 were found, some being as high as 2.0. When the cases were studied after suture the ratio was less than at surgery but still above 1.0 in most instances. On later examination the ratio again rose. These changes in the galvanic tetanus ratio indicated that nerves degenerate and spontaneously regenerate. Histologic material was available in some instances and the presence of neurofibrils substantiated the belief that regeneration had occurred.

DANIEL REED, M.D.

SYMPATHETIC NERVES

The Surgical Treatment of Hypertension. The "Neurogenic" Versus Renal Hypertension From the Standpoint of Operability. Gen. de Talarin and Edson Fairbrother Fowler. *Surgery* 1947, 31 773.

The authors present case histories of 18 patients who had bilateral thoracolumbar sympathectomies for hypertension. In addition, they give a table which groups 50 patients into 3 categories: 8 with nonrenal hypertension, 23 with renal hypertension, and 19 unclassified.

To meet the requirements of a nonrenal hypertension, the following conditions must be present: (1) normal renal structure in a hypertension of long standing; (2) history of a previous thyroidectomy for a toxic goiter; (3) the finding of a medullary or cortical tumor of the adrenal gland.

It is generally assumed that nonrenal or neurogenic hypertension is the ideal type for splanchnic nerve section. Some workers have made an effort to differentiate neurogenic from renal hypertension by the response of the patient's blood pressure to high spinal anesthesia. The authors' experience, however, has not supported the view that the nonrenal hypertensives do better after operation than those with definable renal damage. The authors perform renal biopsies at the time of sympathectomy. The types of renal pathology demonstrated were unilateral hypoplastic kidney, renal trauma, post toxemia, pyelonephritis and streptococcus nephritis.

The conclusions reached are that the so-called neurogenic group has not responded well to sympathectomy, whereas the renal group provided renal damage is not too advanced, has responded favorably. Patients who have had pyelonephritis, post toxemic hypertension, streptococcus nephritis and rheumatic renovascular damage are favorable candidates when the original process has subsided and the resulting renal arteriolar sclerosis remains. Probably the neurogenic type of hypertension is not mediated by the sympathetic nervous system.

DANIEL REED, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Nerve Blocking Therapy for Fractured Ribs. D J Richardson and E. M. Papper *J Thorac Surg.*, 1947 16 432.

The application of regional nerve blocking to the therapy of disease or injury has often been made with the primary purpose of controlling the associated pain. Experience with 230 patients has shown that paravertebral injections of analgesic solutions are indicated to eliminate the pain of fractured ribs and are definitely useful to prevent more serious complications and to reduce mortality.

A variety of solutions was used in the treatment. The most common solution was procaine 1 to 2 per cent, which, in about two-thirds of the cases, was followed by the injection of 1 to 2 c.c. of absolute alcohol. Other solutions used were procaine and ammonium chloride intracaine monocaline and several experimental drugs. The results varied but little.

Following the initial injection there was almost immediate relief of pain in 80 per cent of the cases. Less than 25 per cent of the patients required more than one treatment. Among the patients presented 93.5 per cent had multiple rib fractures and more than a third of the entire series had major complications associated with trauma.

The mortality rate in the complicated cases was 12 per cent and the total mortality was 4.1 per cent. These results indicate that pain relief with nerve block is of significant value in preventing pulmonary infections and death of patients with fractured ribs.

SAMUEL KAHN M D

Treatment of Cancer of the Breast with Estrogenic Hormones (I preparato estrogenico il cancro della mammella) V. Pricolo *Tumori Milano* 1947 33 46

The following conclusions are drawn by the author from observations on 18 patients with cancer of the breast who were treated with estrogenic hormones.

The administration of estrogenic hormones has a definite effect on the primary tumor and the metastases although the effect is only of a transient character. The hormones have a beneficial effect on the painful phenomena and the general condition of the patient. The results are especially noticeable in elderly women, particularly during the menopause. The administration of estrogens should not be considered a substitute for surgery, radiosurgery or the administration of radium.

Estrogens are indicated in inoperable cases because the patient's life may be prolonged.

The author recommends the repeated administrations of moderate doses, such as from 100 to 200 mgm. per series of treatments. High doses should be avoided especially in adolescents and women during the period of sexual activity.

The author usually injects from 5 to 10 mgm of estrogen daily or on alternate days until a total dose of 200 mgm. has been reached. In this manner the toxic effects of estrogen such as nausea, vomiting, grave hemorrhages from the breast or the tumor, metrorrhagia, thermic reactions, dermatitis, and edema may be avoided.

JOSEPH E. NARAT M D

The Use of Testosterone Propionate in the Treatment of Advanced Carcinoma of the Breast. The Treatment of Osseous Metastases. Julian B. Herrmann, Frank E. Adair and Helen Q. Woodard. *Surgery* 1947 22 101

The subsequent course in 3 cases of osseous metastases reported previously (*Ann Surg.*, 1946 123 1023) and the results obtained in an additional 11 patients with osseous metastases are presented.

The favorable results obtained in the present series were with smaller amounts of testosterone propionate than previously used. Dosages successfully employed were 100 and 200 mgm. biweekly and 100 mgm. triweekly. Less satisfactory results were obtained with biweekly doses of 50 mgm. Treatment is usually continued until the patient becomes asymptomatic.

Bone lesions appear to remain quiescent for a variable length of time after androgen therapy is terminated. When pain recurs it can be controlled by additional therapy.

Symptomatic improvement was evident within 3 weeks in 8 of the patients. In 6 patients roentgenologic evidence of calcification in metastatic areas appeared and in some this was discernible in 4 to 6 weeks after institution of therapy. Repeated irradiation of bones does not destroy their power to react to androgen. Effective dosage probably requires sufficient amount to render the patient amenorrheic. In many instances a favorable status may be maintained until pulmonary or liver metastases appear when the patient rapidly regresses and dies within a short time despite the continued administration of androgen.

In one case (Case 8) androgen had first appeared to activate the lesions and later to inactivate them.

There appears to be no relationship with the menopausal status and the results of therapy. Four of the patients were still menstruating, 3 were menopausal and the menstrual status of 4 is not recorded. Ages varied between 39 and 62 years.

Undesirable sequelae are acne, facial hirsutism, and deepening of the voice. Increase in libido is noted in many patients.

FRANK B. QUEEN M D

TRACHEA, LUNGS, AND PLEURA

Adenomas Arising from Small Bronchi not Visible Bronchoscopically. Herbert C. Moler and Walter W. Fischer *J Thorac Surg* 1947 16 392

Bronchial adenomas usually occur in the larger bronchi, and can be visualized through the broncho-

scope. The diagnosis is often established by microscopic examination of biopsy material removed endoscopically.

Five cases are reported, in which the tumor was located in a branch bronchus not accessible to the bronchoscope. In each instance, the tumor was large enough to be visible on x ray. Since the tumor did not arise from a large bronchus in any of the cases reported, none of the patients had any history or symptoms of secondary pulmonary suppuration. Three of the patients were asymptomatic, one had several hemoptyses, and one had slight pain in the chest.

In 4 of the cases the tumor was located near the hilar area. These were treated by lobectomy. In the fifth case, the tumor was at the periphery of the lung close to the diaphragm in this case a partial lobectomy was done. All the patients are now well.

Grossly bronchial adenomas are moderately soft, being much softer than the typical carcinoma. Occasionally lobulation is present. The tumor is usually reddish-brown in color. If a portion of the tumor projects into the mediastinum, small veins often cross its surface.

In most instances, a portion of the tumor can be enucleated from the adjacent pulmonary tissue or mediastinal tissues, but there is no cleavage plane in the region of the bronchus of origin. If the tumor projects into an interlobar fissure, it may be noted that when the pleura is divided over the tumor that portion of the tumor which projects towards the adjacent lobe can be readily freed, so that lobectomy is feasible. Pneumothorax is not necessary in cases of bronchial adenoma that are typical and so located that the tumor can be completely removed by lobectomy. In none of the 5 cases reported was there involvement of the regional lymph nodes.

SAMUEL KAHN, M.D.

An Unusual Hamartoma (So-Called Chondroma of the Lung) Morris A. Simon and Harry C. Balloon. *J. Thorac. Surg.* 1947 16 579.

Although small so-called chondromas in the lung are encountered occasionally as incidental findings at autopsy or on routine x rays, the occurrence of relatively large, intrapulmonary cartilaginous masses which produce clinical symptoms is quite uncommon. Usually so-called chondromas vary from a few millimeters to 3 to 4 cm. in diameter but a few tumors varying from 5 to 15 cm. in diameter have been seen. They may be subpleural in position, or may lie near the hilum or elsewhere in the lung. They are firm, dense, tend to be somewhat lobulated, are sharply demarcated, and are gray and glistening on section. The smaller tumors rarely if ever produce clinical symptoms.

These so-called chondromas are not pure cartilaginous tumors, but contain abnormal mixtures of the elements normally encountered in the bronchial wall. They are, therefore, more properly referred to as hamartomas or hamartoma chondromatous polyps.

Although hamartomas of the lung is usually considered to be a benign, slow growing tumor malignant changes may occur. In the case reported, the tumor was of unusual size, produced constant pain and mucopurulent expectoration, and presented a roentgenologic appearance which strongly simulated the usual bronchogenic carcinoma.

SAMUEL KAHN, M.D.

Cupola Tumors. "Ewen-Gösta Sjöberg. *Acta. med. scand.* 1947 143 38.

Over 80 cases of cupola tumors have been described in the literature up to 1942. This type of tumor was first described by Pancoast in 1932. Horner's syndrome first described by Hare in 1838, was based on a case of superior sulcus tumor (cupola tumor).

The author reports 5 cases of this type of tumor: (1) a squamous cell carcinoma, (2) a pleural endothelioma, (3) bronchial carcinoma, (4) bronchial carcinoma. In the fifth case a biopsy was not made. Four of the 5 cases exhibited Horner's syndrome.

One case, that of a bronchial adenocarcinoma, developed entirely above the pleural cupola and, except for a narrow adhesion, was entirely unconnected with the lung. It was also remarkable because of the lack of roentgenographic changes characteristic of cupola tumors. The author prefers this designation because "they are always intimately connected with the cupola pleurae."

Röntgen therapy had a good palliative effect in 3 cases. Unrelenting brachialgia and Horner's syndrome are the most important symptoms.

FRANK B. QUINN, M.D.

Bronchogenic Carcinoma; a Clinicopathological Study of 36 Autopsied Cases Seen at the Brooklyn Cancer Institute between 1927 and 1945, Inclusive. William A. Henkin. *Ann. Int. Med.* 1947 27: 243.

Bronchogenic carcinoma constituted 9 per cent of all malignancies studied at autopsy at the Brooklyn Cancer Institute, Brooklyn, New York. Eighty-eight per cent of the carcinomas were seen in males of a mean age of 55 years.

All primary bronchogenic carcinomas arise from an undifferentiated stem cell located in the basal layer of the bronchial epithelium. The tumor is an adenocarcinoma, a squamous-cell carcinoma, or an undifferentiated or anaplastic carcinoma, depending on the type and degree of differentiation of the original stem cell. Tumors falling into the different histological categories have similar clinical courses, metastasize in a similar manner and show no consistent variations in their response to radiation therapy.

Because different series, classified by equally competent pathologists, show tremendous variations in the percentages of the various histological types, classifications may be regarded as of academic rather than of practical significance.

The earliest and most common symptom, frequently overlooked for months, is a nonproductive

cough. The growing tumor is a foreign body which the bronchus attempts to extrude.

Physical examination and chest roentgenograms show no evidence of the disease in this stage although bronchoscopic biopsy is often possible at this time. In middle-aged individuals wheezing or asthmatic breathing should initiate a thorough search for bronchogenic carcinoma as the growing tumor begins to cause partial obstruction of the bronchus and the segment of lung distal to the affected bronchus becomes emphysematous. Usually the period of emphysema is of short duration and remains unrecognized while the enlarging tumor gradually produces complete bronchial obstruction and atelectasia. If the occluded bronchus is sufficiently large there may be a considerable shift of the mediastinum to the affected side, and a real decrease in functioning lung volume and dyspnea will develop. Almost simultaneously secondary infection develops within the atelectatic segment as necrotic tumor tissue mucus, pus, and bacteria accumulate. Leukocytosis fever and anemia appear. This cycle is responsible for the dangerous diagnosis of "recurrent pneumonia" which has been made too frequently in the face of an advancing malignancy.

Roentgenologic diagnosis is not always easy. A definite diagnosis of bronchogenic carcinoma is made in about 60 per cent of the cases.

In the last analysis bronchogenic carcinoma can be established only by the microscopic examination of an adequate biopsy specimen. In early cases the specimen is obtained either at bronchoscopy or at thoracotomy. In later stages subcutaneous nodules or involved lymph nodes can be biopsied. Pleural fluid may contain cells whose appearance is suggestive of malignancy. Sputum is rarely examined and almost never shows malignant cells when studied by older techniques. However aspiration of bronchial secretions at bronchoscopy and staining by Papanicolaou's method is a procedure which should be performed more often.

The mean and the median life expectancy in this series were only 8 months from the onset of symptoms to death. No patient lived longer than 28 months after the appearance of symptoms.

Treatment is either surgical or roentgenological, or both.

If trained thoracic surgeons are available and there is no discoverable evidence of metastasis, the earliest possible surgical intervention is imperative. Interval roentgen study of a suspicious pulmonary mass or hilar enlargement dooms the case that is suitable for resection.

Every case without metastases or evidence of local invasion of vital structures should have the benefit of an exploratory thoracotomy. Roentgen therapy although merely palliative with the generally available 300 kilovolt apparatus, should be given as early as possible after the determination of nonresectability. Tumor doses above 5,000 roentgens should be administered if maximum benefit is to be derived.

STEPHEN A. ZIEGLER, M.D.

Primary Carcinoma of the Lung, with Invasion of the Ribs. Frank Philip Coleman. *Ann Surg* 1947 126 156

Osseous invasion is present in probably between 5 and 10 per cent of all patients with carcinoma of the lung. The majority of the pulmonary carcinomas which secondarily invade adjacent ribs or vertebrae are of the squamous cell type. The author describes the case histories of 6 patients in whom such squamous cell tumors were observed. Pericostal invasion of the soft tissue of the chest wall without osseous extension had occurred in an additional patient in whom the tumor was an adenocarcinoma.

Peripheral pulmonary squamous cell carcinoma invades contiguous structures grows slowly and metastasizes late in the course of the disease. Because of this favorable pathologic behavior it is emphasized that adjacent rib invasion does not relegate carcinomas of this type into the group of incurable tumors. Block excision of the chest wall leaving a margin of healthy tissue attached to the involved structures plus total pneumonectomy and excision of the regional lymph nodes is the desired treatment in such cases.

Other than pain there are few symptoms until late in the course of the disease. Tenderness over the affected rib is usually present. Rib destruction is revealed by over-exposing the roentgen films. Direct biopsy of the rib will establish a tissue diagnosis but it carries with it the danger of soft tissue implantation in apparently operable patients.

Exploratory thoracotomy is the method of choice in selected cases for determining tissue diagnosis and operability. The pleural cavity is entered a rib and a full rib interspace below the lesion. Involvement of the brachial plexus, sympathetic trunk, phrenic nerve or the transverse processes of the vertebrae contraindicate curative surgical attempts but palliative resection may be considered in view of the associated severe pain.

Five of the 7 patients whose cases are reported by the author were subjected to block excision of the chest wall and pulmonary resection. A total pneumonectomy was carried out in 4 patients and a palliative lobectomy in 1 patient. There was one operative death, and the patient with the palliative lobectomy lived for a period of 11 months. The 3 remaining patients are living and well—one 6 years one 2 years and one 5 months after operation.

ORVILLE F. GARDNER, M.D.

Sequelae of Pneumotomy (Séquelles de pneumotomie) Marc Iselin. *Helvet chir acta*, 1947 14 147

Recent advances in chemotherapy have rendered pneumotomy almost superfluous as a treatment for lung abscess. However some cases fail to respond to penicillin, and pneumotomy may save the patient's life if not too long delayed. The mortality rate of this operation is estimated at about 25 per cent but it is due to the sequelae of operation rather than to the intervention per se. Poor results of the operation are notably diminished if it is performed in

the earlier stages, before the development of chronic disease. Among the lesions responsible for nondrains following pneumotomy may be mentioned bronchial fistulas, residual pulmonary cavities, bronchial dilatations and pyocarcinosis.

The surgical pathologic anatomy of these complications is discussed at length including that of the skin wound and surrounding bone structures. Frequently multiple cavities are present before the pneumotomy and may require repeated pneumotomy via the same or other routes for final obliteration. In the case of symptomatic fistula, treatment must be directed to the cause whether this be multiple abscesses, bronchial dilatations, or abscesses superimposed on bronchial dilatation or pyocarcinosis. For residual fistula, muscle flaps from the vicinity may be used to fill the cavity. In untreated symptomatic fistula death usually ensues within 2 years from chronic suppuration, pneumonic phases, secondary hemorrhage or cerebral abscess. In residual fistula the chief danger is from secondary hemorrhage which may cause sudden death. Even though the fistula is apparently well tolerated, its elimination is imperative. Differential diagnosis includes elimination of tuberculosis and cancer. In symptomatic fistula, tomography and bronchography will reveal the condition of the lung and bronchi. Roentgenoscopy at frequent intervals is a valuable diagnostic aid. In residual fistula a lipiodol bronchogram is necessary to ascertain the condition of the bronchial tree.

The surgical methods of treatment in order of increasing importance are as follows: débridement of the wound, repeated pneumotomy, plastic muscle flap operation, and lobectomy or pneumonectomy.

Symptomatic lesions must be treated in as rapid sequence as possible, only enough time being left between the operations for the reaction from the last to subside. Collaboration of the physician and surgeon in this respect is most important.

The choice of procedure will depend upon the lesions found. In the presence of a retracted wound with retention and hemorrhages, débridement under local anesthesia is indicated with incision of the scar tissue and liberation of the fibrous bands binding the skin to the deeper tissues. During operation poorly exposed cavities may be discovered and may require incision or even additional rib resection. Following wide exposure, the wound may be powdered with septolix and packed with gauze. Débridement was done 17 times in 13 patients, and 3 times in 1 patient. Repeated failure of this procedure is one of the major indications for the plastic muscle operation.

A secondary abscess close to the pneumotomy wound may be approached through the same incision following débridement. If the abscess is at a distance from the original wound a new approach may be required. In 1 case as many as 4 incisions had to be made. In the attempt to open an abscess once it is located great care should be employed to keep trauma to the lung tissue at the minimum. "Cuneo-resection" with the thermocautery or electric bistoury too often involves trauma which leads to a fatal issue.

Should parenchymatous and bronchial suppuration persist, excisional or typical lobectomy is indicated if the general condition of the patient permits. Because of the pulmonary breach, an aseptic intervention is impossible and the operation is rendered still more difficult by the presence of regenerated bone and adhesions. Medical treatment is therefore recommended in these cases, and at least 1 patient who was believed lost was saved by this method.

In cases of fistula or residual cavity a pedicled muscle flap from the vicinity may be used to fill the bronchial orifices, but this procedure is merely palliative and cure will not be complete if bronchial dilatation persists. Only 1 death was attributed to this type of treatment. The radical procedure for these lesions consists in lobectomy which at present, with the aid of penicillin, permits complete cure in 3 weeks. Because of parietal changes this operation is difficult and dangerous. Adhesions are usually dense, the pneumotomy wound may be placed inconveniently and, if more than 2 rib segments are wanting, the incision may be difficult to close. Diffuse induration may be discovered beyond the planned field of operation which necessitates a pneumonectomy. In such cases a prompt decision is imperative if the life of the patient is to be saved. Too much blood and time may be lost in performing a futile lobectomy.

If the general condition is good the operation may be selected according to the anatomic findings; if not, no major operation can be attempted until proper measures have been instituted to strengthen the patient.

The pedicled muscle flap is indicated in tuberculous lesions in which excerals might lead to dissemination of the bacilli. The residual fistula ordinarily left after this procedure will close in time. When the cavity is larger than a small fist, muscle transplantation will not suffice. In 1 case, healing took place after repeated plastic interventions over a year and in another similarly treated case the bronchial fistula persisted but its caliber was greatly diminished. Complete success was obtained in 2 cases in which lobectomy was done in the first place.

Lobectomy of the upper lobe is extremely difficult and dangerous, whereas the plastic operation employing a pedicled muscle flap yields good results. In lower lobe and lateral lesions, excerals is preferable.

For a successful plastic operation, the fistula must be permeable both on inspiration and expiration. Otherwise emphysema and purulent effusion may develop following operation in spite of the use of penicillin.

Other conditions permitting excerals is indicated when bronchial dilatations are found in the vicinity of the residual cavity or at a distance from it. In their absence and barring other contraindications, the plastic operation is preferable. These indications will, of course, be influenced by the constant advances being made in the technique of excerals with diminished chances of hemorrhage and shock. The strongest argument against excerals is the impossibility of

locating lesions before operation so that pneumonectomy may be required where lobectomy was planned. Advances in chemotherapy permit an earlier evaluation of the probable results of medical treatment so that when failure appears imminent a pneumonectomy can be done at a stage when the mortality and morbidity of this operation are still low and good results can be expected.

EDITH SCHANCHE MOORE.

The Use of Prostheses to Prevent Overdistention of the Remaining Lung following Pneumonectomy
Julian Johnson, Charles K. Kirby, C. S. Lazatin, and J. A. Cocke. *Surgery* 1947 22 179.

The clinical experience and experimental work of these authors indicate that it would be desirable to prevent mediastinal shift following pneumonectomy and thus avoid overdistention of the remaining lung. This can be accomplished by an extensive thoracoplasty. In the presence of infection the thoracoplasty must be done. In the absence of infection it is desirable to use some method which is less extensive than a thoracoplasty whereby overdistention of the remaining lung can be prevented.

It is suggested that a noncompressible prosthesis may be introduced into the pleural cavity at the time of pneumonectomy as a means of preventing postoperative mediastinal shift and overdistention of the remaining lung.

Two types of prostheses have been studied in the dog: (a) a solitary large hollow metal prosthesis of zirconium, and (b) multiple small hollow plastic balls of methyl methacrylate (lucite).

The studies made indicate that hollow balls of methyl methacrylate (lucite) make a satisfactory filling material to place in the pleural cavity following pneumonectomy. They cause minimal reaction in the pleura and offer a convenient means of filling pleural cavities of various sizes.

HEART AND PERICARDIUM

Anomaly of Aorta Simulating Mediastinal Tumor
David B. Corcoran and Frank Philip Coleman.
J. Thorac. Surg. 1947 16 427.

Röntgenologic examination is the most important method of diagnosis of solitary tumors of the mediastinum. It offers valuable information pertaining to the type of the tumor by localizing the mass, revealing its relationship to adjacent structures, and by establishing the presence or absence of pulsation. Diagnostic roentgen therapy also plays a role in the differential diagnosis in certain cases, by determining radiosensitivity.

A case of unusual interest is reported in which a unique anomaly of the aorta, simulating a mediastinal tumor was found.

SAMUEL KAHN, M.D.

Complete Division for the Patent Ductus Arteriosus.
Robert E. Gross. *J. Thorac. Surg.* 1947 16 524.

A follow up study of 43 patients who were treated by various types of ligation 'in continuity' for

Fig. 1 (Johnson et al.) A dog sacrificed 3 months after left pneumonectomy and introduction of 24 one inch lucite balls into the pleural cavity. The right lung was not overdistended. There was just enough fluid present to fill the space between the balls (35.0 c.c.) There was minimal reaction of the pleura.

patent ductus arteriosus shows that 80 per cent of the patients obtained complete closure of the ductus. In about 10 per cent of the cases the fistula was re-established when the ligatures apparently cut partially through the ductus. In the remaining 10 per cent, the ligatures were not tied tightly enough so that a small shunt persisted at the close of the operation. Most of the patients were benefited because the work of the heart was tremendously decreased and in some cases a streptococcus viridans infection was permanently cured. However permanent closure of the shunt can only be assured by complete division of the ductus.

An anterior approach is made, and the third inter-space is utilized after the second and third costal cartilages have been divided. The superior mediastinum is incised longitudinally one half inch posterior to the phrenic nerve. The vagus and left recurrent laryngeal nerves are spared from injury. Lymph nodes fat and areolar tissue must be cleared away from the aortic arch and the pulmonary artery so that the intervening ductus can be clearly visualized. After the ductus has been freed of areolar tissue and has been cleared of any investing membrane, four clamps are applied and the ductus is divided between the middle two. The clamps used are standard Crile clamps 3/4 inches in length the jaws of which

have been ground off on both sides so that the surfaces are nearly parallel and the jaws thinner than those of stock instruments.

The pulmonary side of the ductus is closed first. The presenting clamp (the one nearest the operator) is removed thus providing a small cuff of ductus wall 2 or 3 mm. in length. This cuff is sewn over and over with a continuous 5-0 Deknatel silk suture carried on a small atraumatic needle. The aortic cuff produced by removing the uppermost clamp is treated in a similar manner. A second row of adventitial sutures is unnecessary.

After the pulmonary and aortic ends have been sutured a gauze sponge is inserted into the interval between the pulmonary artery and the aorta and the remaining pulmonary clamp is removed. The pack is held in place several minutes to allow blood to coagulate between the intima of the sutured end of the ductus. The aortic clamp is removed similarly. Only in a few cases is it necessary to apply additional sutures. The mediastinum is closed by repairing its parietal pleura with interrupted silk sutures.

Complete division of the ductus arteriosus has been carried out in 90 patients ranging in age from 2 to 46 years. There were 2 surgical deaths—one 2 weeks after operation from an overwhelming staphylococcal mediastinitis, the other in a 26 year old female with advanced cardiac decompensation.

Complete division is especially indicated in adults beyond 18 to 20 years of age. The ductus is frequently unyielding, is difficult to compress, and has an exaggerated pulsation transmitted to it by a sclerotic and fixed aorta. Under such circumstances ligation in any form will occasionally lead to a partial recurrence of the fistula. Even in infants, the author believes that complete division is the superior method although it is admitted that in children in whom the ductus is soft, yielding, elastic, and easily compressible, ligation can almost always be relied upon to produce a permanent closure. Complete division of the patent ductus has been so completely satisfactory that the author has abandoned all forms of ligation of the vessel. ORVILLE F. GRIMES, M.D.

Complications of the Surgery of Patent Ductus Arteriosus. John C. Jones. *J. Thorac. Surg.* 947 161 305.

Complications of the surgery of patent ductus arteriosus in a series of 61 successive patients are reviewed. In 53 of the cases the ductus was ligated in continuity, in the remaining 8 it was divided and sutured. Virtually all patients developed post-operative effusions, but in only one third of the cases was aspiration deemed necessary. Atelectasis occurred in 5 patients, each time in the left lower lobe. Left recurrent nerve paralysis occurred in 3 patients. It was persistent in 2 patients, and in patient recovery was noted within a few weeks after operation. Two of the patients developed empyema thoracis, preceded by pneumonia in only 1 patient.

There were no wound infections. The anterior approach utilizing the second interspace has been

abandoned because of the high incidence of keloid scars. A posterolateral incision with resection of the fourth or fifth rib is recommended.

Sudden copious hemoptysis was a serious complication in 2 patients whose case histories are recorded. Both patients, aged 35 and 11, had repeated episodes of gross hemoptysis. One patient remains well after exhibiting hemoptysis of varying degree for a period of 7 months, and occasional streaking of the sputum for a further period of 15 months. Exploratory thoracotomy performed on the 11-year-old patient revealed an aortobronchial fistula resulting from erosion by the silk umbilical tapes used in ligating the ductus. In both patients the ductus has remained closed. Since this experience the mediastinal pleura has been closed in all cases so that the knots are buried to protect the mediastinal aspect of the upper lobe. The latter procedure, however, will not prevent erosion of the aorta or possible aneurysm. Such a complication is considered an argument in favor of complete division of the ductus arteriosus.

There were 2 deaths in the series—one from Staphylococcus aureus endocarditis 48 days following ligation. In the first case, autopsy revealed a re-established fistula between the pulmonary artery and the aorta, and an aneurysm of the ductus. The ligatures had cut through the wall of the ductus, and a superimposed blood stream infection resulted in vegetations on both the pulmonary artery and the aortic wall. The other death was an operative mortality from cardiac arrest occasioned by a considerable loss of blood at a rapid rate. At autopsy cardiac pathology consistent with that found in rheumatic fever was revealed.

Failure to tie the tapes tightly enough to occlude the lumen of the ductus completely is the probable explanation of the failure to obliterate the continuous murmur which occurred in 5 cases. In 5 other cases, a recurrence of the continuous murmur detected from 5 to 6 weeks after surgery is explained by re-establishment of the fistula after the tapes had partially cut through the walls of the ductus.

ORVILLE F. GRIMES, M.D.

Bullet Wounds of the Heart (Heridas de bala del corazón). Leonidas Aguirre Mac Kay Arch. Soc. Med. Santiago 1947 3 393

This article records the experience of the emergency service for the City of Santiago de Chile between 1933 and 1945 (13 years). Fourteen patients with bullet wounds of the heart were treated with 3 survivals. One of the 14 patients was not operated upon.

The subject of heart wounds is briefly reviewed with ample use of tables to illustrate the types of wounds, other associated wounds, the age, sex, state of sobriety, and the length of time elapsed between the wounding and the operation. These tables are taken not only from the material under discussion, but from records of the Medicolegal Institute and from the literature. No significant details of tech-

nique are included beyond illustrations of several accepted surgical approaches.

A case is reported in which a heart wound produced by a bullet was successfully sutured

HIRAM T. LANGSTON M.D.

Heart Catheterization. A. L. Johnson D. G. Wollin, and J. B. Ross. *Canad. M. Ass. J.*, 1947 56 249.

The importance of more exact diagnoses of congenital heart lesions has been emphasized by the advances which have been made in surgery for congenital heart defects. Heart catheterization has been used by the authors in 17 children ranging from 19 months to 16 years. By this method all four heart chambers and the pulmonary artery and vein have been entered.

Forsmann in 1929, is credited with the first heart catheterization but it was not until the work of Courmand and Ranges in 1941 that its many possibilities were recognized. Brannan, Dexter and Baldwin also have reported recent works on this subject.

A ureteral catheter is introduced through a nick in the antecubital or saphenous vein. It is a special catheter with a curve in the distal end. This gives the operator some control in directing the tip. Under fluoroscopic control the catheter is passed into the right auricle, the right ventricle and pulmonary artery.

Either arm may be used but the catheter seems to pass more readily past the origin of the innominate vein on the left. A slow drip of saline through the catheter keeps the lumen patent. Blood samples or pressure readings are taken through a three way stop cock. The patient should be heparinized at the start of the procedure and a clotting time of 10 to 20 minutes is maintained for 24 hours afterwards. From 5,000 to 10,000 units of penicillin are given intramuscularly every 3 hours for 48 hours. Mean pressure readings are taken with a saline manometer and Tyco's dial. Blood samples for oxygen determinations are withdrawn under oil and run by the Van Slyke method. An x-ray picture is taken at every site at which a blood sample is withdrawn. At the conclusion of the procedure blood is withdrawn from the femoral artery for an oxygen consumption determination with use of the Benedict Roth apparatus.

Morphine and scopolamine and a barbiturate were used for preoperative medication. Intravenous morphine and avertin or pentothal were used as anesthetics in children under 3 years of age. The older children needed no anesthesia.

This method is safe as some 1,200 procedures have been carried out without a fatality. No arrhythmias other than occasional extra systoles have been reported. The authors had one patient who developed paroxysmal tachycardia during the procedure. Only occasional slight thrombophlebitis of the brachial veins has been reported. One of the authors' patients, a 19 month old sickly infant, died 1 month

after heart catheterization. A clinically unsuspected organized thrombus of the inferior vena cava, right renal vein, and both common iliac veins were present, as well as a large thrombus attached to the right auricular wall.

Of the 17 patients 4 were cyanotic, 9 were considered to have interventricular septal defects, none were cyanotic in 1 patient the persistence of a left superior vena cava was demonstrated.

Arterialized blood in the right ventricle or blood with a significantly higher oxygen content than that found in the right auricle is evidence of a ventricular septal defect. The case reports and x rays of several examples are given.

An example of a patent ductus arteriosus and 2 cases of auricular septal defects are discussed.

In some instances, placing the catheter under fluoroscopic vision enables one to estimate the size of the ventricles or auricles.

Based on their limited experience and on the few cases in the literature, the authors believe that heart catheterization appears to be a useful adjunct to the investigation of congenital heart disease.

ROBERT R. BICKLOW M.D.

Traumatic Pneumopericardium (Le pneumopéri-cardé traumatique) Eric Nègre *J. Chir. Par.*, 1947 63 307

Traumatic pneumopericardium produces its characteristic clinical syndrome of cardiac compression in addition to those symptoms which usually accompany all penetrating thoracic or thoracoabdominal wounds. In many instances the elements of the compression syndrome are not easily recognized in the complex picture of shock and acute anemia.

The pathophysiology of pneumopericardium is dependent upon the compressibility of gaseous substances and upon the exceptional faculty of the pericardium for resorption, which is superior to that of other serous cavities. However, intrapericardial gas may be under considerable tension as in the case of hemopneumopericardium or of gas bacillus infection in which gas is continually produced in a nonextensible chamber. In the latter 2 instances the symptoms of cardiac compression rapidly ensue.

The compression syndrome of pneumopericardium is manifested by both respiratory and cardiovascular distress. Dyspnea is constant and respirations are rapid, short, and superficial. Anginal type of pain is common. Tachycardia, fall in arterial tension, increased venous pressure, deathly cyanosis or pallor of the face and turgescence of the jugular veins completes the picture of compression. A precordial zone of tympany may sometimes be found but in most cases an intrapericardial or mediastinal outpouring of blood will mask such a sign. The roentgenological examination will confirm the existence of pneumopericardium alone or in association with a hemopericardium.

Pure pneumopericardium is rare and when present is produced by a rather small cutaneous wound with a short course directly to the pericardium. The more

segments were resected up to the chondrosternal cartilage of the ribs three fourths or four fifths of which had previously been resected via the posterior paravertebral route. In a very few cases these anterior segments were resected before the posterior segments. Usually the transverse apophyses of the second third fourth, fifth and sixth ribs were resected. Apicolysis was added in some cases following the bony resection.

The mortality rate during the second five year period was greatly reduced probably because of advances in bronchology anesthesia blood banks, as well as in radiologic and surgical technique.

Fifteen patients died following the first stage of the operation. Of 9 patients dying after the second stage, 1 had previously been operated on the contralateral side. Of 4 who died after the third stage, 1 had already been subjected to two stages on the other side. Twelve deaths were attributed to operative shock, and occurred early in the series before the day of blood banks and bronchoscopic drainage. Intratracheal anesthesia has also served to reduce the mortality. Other causes of death included bilateral parenchymatous reaction, homolateral reaction, contralateral reaction, secondary empyema, and infection of the wound as well as accidental injury of the parietal pleura and empyema, fulminant hemorrhage from the wound anesthetic shock before the fourth stage secondary uremia, and incompatibility of the transfused blood.

Patients of the third or fourth class are more likely to have residual caustics even after several stages of thoracoplasty. However a number of patients survived and some were even able to resume their occupation.

Of 303 patients surviving operation 197 or 50.3 per cent, are living and of these, 131 patients or 30.6 per cent, are working. Thirty four or 10.3 per cent, are at home either because they are afraid to go back to work or because they are still suffering from

tuberculosis of one form or another. Thirty-two patients or 0.6 per cent, are still hospitalized, and 77 patients have died from the results of operation or spread of the disease to the other lung or other organs. In many cases in which work was resumed too early the disease spread to the other lung. The patients died of causes not related to the operation or tuberculosis. Fifty-three patients or 15.7 per cent, could not be traced.

The series of 58 cases of tuberculous empyema was divided into two classes, the good risks being those presenting a restricted pleural space with no detachment in the upper fourth, no evident bronchopleural fistula, and no marked pachypleuritis. Only 36 per cent of the series belonged in this class. It was noted that artificial pneumothorax had been employed in 35.60 per cent, of the 58 cases in which tuberculous empyema developed. Thoracotomy for drainage as necessary in 30 cases or 51.7 per cent. Extrapleural thoracoplasty sufficed in 33 cases. Thirty patients were subjected to a Schede thoracoplasty. Following resection of a portion of the parietal pleura, the infected pleural cavity was curetted. This intervention causes considerable surgical shock which may be difficult to control.

In 12 cases two types of thoracoplasty were done in the different stages. In some cases it was necessary to use a musculoaponeurotic graft to fill the pleural cavity.

The mortality of these patients without thoracoplasty was very high. Nevertheless, in 1945, 35 per cent of the patients were not only alive but working. The operative mortality rate was 15.5 per cent. Seventeen other patients have died subsequently and 8 could not be traced.

It is evident that thoracoplasty is the only successful treatment for certain types of tuberculosis of the lungs and pleura. The risk is slight and many patients recover and can resume work.

EDITH SCHAEFER MOORE.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Femoral Hernia with Gangrenous Bowel Clarence
Dennis and Richard L. Varco *Surgery* 1947 22
312.

The published mortality rates for strangulated femoral hernia are high. Only one report in the literature mentions a mortality rate as low as 25 per cent. The authors believe that the high mortality statistics are due mainly to the conventional method of exposing and opening the hernia sac either by externalization or resection and primary anastomosis in the contaminated field.

An alternative method of management is presented. Preoperative attention is directed toward re-establishing correct water and electrolyte balance. Gastric suction is instituted. Although the lapse of a few hours might increase the likelihood of frank gangrene in the strangulated bowel it is wiser to attend to the altered fluid state.

With the use of local block anesthesia, a vertical incision is made over the bulge in the groin and cautiously carried down to the peritoneal sac. The contents of the sac can be visualized through the remaining wall. Should gangrenous bowel be recognized, dissection in this area is discontinued and an incision is made 2 centimeters above the inguinal ligament and parallel to it. The vertical line is continued upward to form a T-shaped incision. The incision is developed and the peritoneum is opened parallel with the oblique skin incision. From this vantage point, the viscera entering the hernia may be readily identified. If omentum is involved it is easily divided and ligated close to the neck. If gangrenous small bowel is present in the sac, Ochsner clamps are placed across the two limbs and the bowel is divided between each pair with the canter. The inguinal ligament is then divided and split laterally leaving enough aponeurotic tissue applied to the neck of the sac to prevent relaxation of the neck and release of the soiled content. The entire contaminated area can then be removed intact without soiling of the operative field (Fig. 1). Primary end-to-end anastomosis of the limbs of the bowel can then be accomplished.

Closure of the peritoneal defect in the repair of the hernia is easily accomplished because of the mobility of the peritoneum in this area. The margins of the internal oblique and the transversus muscles are sutured to Cooper's ligament as far lateral as the femoral vein and to the inguinal ligament lateral to that point. The inguinal ligament is restored by approximating it without tension to the lacunar ligament and to Cooper's ligament.

The importance of avoiding contamination is paramount. By recognizing the state of the contents through the intact hernial sac, contamination of the operative field is prevented. Experimentally it has

Fig. 1 (Dennis and Varco) Sac removed

been shown that the abdominal fluid and venous blood in cases of strangulating obstruction contain depressor substances. It is therefore important to resect the gangrenous segments of intestine without releasing the neck of the sac.

The authors defend their sectioning of the inguinal ligament by stating that the repair as indicated has been successful in their hands. Closed aseptic end-to-end anastomosis is recommended.

The authors present 10 cases in which this plan of management was carried out. Two patients have died, one of cardiac failure and the other of a ruptured aortic aneurysm. The other patients are living and well. One patient developed a recurrence as a direct hernia 2 years after repair.

ORVILLE F. GRIMES, M.D.

GASTROINTESTINAL TRACT

Effect of Enterogastrons on Mann-Williamson
Ulcers in Dogs. H. C. Saltzstein, David J. Sand-
weiss, John M. Hammer, Edward J. Hill, and
Henry J. Vandenberg, Jr. *Arch. Surg.*, 1947 55
135

In this study the authors attempted to evaluate the effect of orally administered enterogastrone on a series of 15 dogs in which jejunal ulcer had been produced by the Mann-Williamson operation. At

the time of this report the average survival time in the enterogastrone series was 96 days while that of the control series was 71 days. The longest survival time in the enterogastrone series was 59 days, while that of the control series was 135 days. The shortest survival time in the enterogastrone series was 25 days compared with 53 days for the control group.

Eleven of the enterogastrone treated dogs died with jejunal ulcers with an average survival time of 97 days. Of the 11 dogs with jejunal ulcer, 10 had perforated ulcers and generalized peritonitis which accounted for death.

In the control series all of the dogs showed ulcer at autopsy and in 73 per cent the ulcer had perforated.

Therefore, it is concluded that oral enterogastrone has some beneficial therapeutic effect on experimental Mann-Williamson ulcers in dogs.

HAROLD LAUFMAN, M.D.

Effect of Vagotomy on Mann-Williamson Ulcers in Dogs. H. C. Saltzstein, David J. Sandweiss, John M. Hammer, Edward J. Hill, and Henry J. Vandenberg, Jr. *Arch. Surg.* 1947 55 130.

While 28 control dogs survived the Mann-Williamson operation for an average of 71 days, 13 dogs on which vagotomy plus the Mann-Williamson operation were performed survived only 51 days after the Mann-Williamson operation and 44 days after the vagotomy. Of the controls, 100 per cent showed ulcer at autopsy. Seventy-two per cent of these died of perforation with peritonitis. Among the vagotomized animals, jejunal ulcers developed in 6 of the 8 that lived more than 1 month after the Mann-Williamson operation. An inflammatory reaction of varying severity was found in the upper part of the jejunum in 7 of 13 dogs on which Mann-Williamson operations and vagotomy were performed. There was no correlation with the survival time. Gastric dilatation was present in 9 of the 13 dogs.

It is therefore concluded that vagotomy does not have a favorable effect on the ulcers produced by the Mann-Williamson operation. Since jejunitis was present in 60 per cent of the vagotomized dogs it is suggested that it may be an explanation for the diarrhea following this operation.

HAROLD LAUFMAN, M.D.

Resection of the Vagus Nerves for Ulcer; An Interim Evaluation. Operative Technique and Hospital Management. Francis D. Moore. *Arch. Surg.* 1947 55 104.

In this article the author outlines the technical procedures which he employs in vagus resection for ulcer as well as the hospital management of patients. Eighty-seven per cent of the author's 83 patients had good results and are well satisfied with their operation from 3 to 30 months postoperatively. Five patients had a frankly poor result either with a demonstrable recurrence or symptoms of ulcer. Five other patients had sufficiently severe side effects, consisting of diarrhea or other gastrointestinal manifestations, to detract materially from their satis-

faction with the result. All but 1 of the authors' patients were operated on through the thorax. Only 3 postoperative posterior gastroenterostomies have been necessary. Of 73 patients who underwent thoracic operations, 40 had no discomfort of the chest after the first few postoperative days, 31 had minor discomfort and 3 had major chest or intercostal pain.

The postoperative management extends through the first 3 postoperative months and consists essentially of giving the stomach an easy mechanical job to perform and allowing it a complete 12 to 16 hour rest if the presence of fullness or diarrhea indicates some defect. Many patients who have been untidied over a bout of motility symptoms have remained well subsequently. The author believes that although there is a strong temptation to carry out gastroenterostomy under these circumstances, it can usually be avoided.

The 19 patients in this series who had gastroduodenal stomas either primary or secondary had the same incidence of diarrhea and fullness as the series of patients with duodenal ulcer. This is another reason for not performing gastroenterostomy routinely. As treatment for frank obstruction it is usually effective as a means of avoiding gastrointestinal side effects. It is ineffective. The author describes his technique for the thoracic approach to the vagus nerves.

If care is taken in dietary management, the prolongation of hospitalization due to poor emptying of the stomach need only constitute a minor problem. The prevention of pulmonary complications involves early ambulation, the use of blow bottles, encouraging the patient to cough and to take deep breaths, and moving the patient freely in bed. To prevent postoperative dilatation of the stomach the author gives less than 1 ounce of liquid per hour for 3 or 4 days. The diet is then cautiously increased with daily aspirations of the stomach. The diet is "wet back" if a significant residue forms. The author leaves the Levine tube in place on suction for 48 hours in most cases. The patient is never discharged from the hospital following transthoracic vagotomy prior to the twelfth day.

By performing gastroenterostomy as rarely as possible the author hopes to be able to better evaluate the therapeutic effect of the vagus resection. The routine performance of gastroenterostomy with each vagotomy confuses the therapeutic effect, since gastroenterostomy in itself has such an effect in most instances.

HAROLD LAUFMAN, M.D.

Section of the Vagus Nerves to the Stomach in the Treatment of Benign Gastric Ulcer. Paul V. Harper, Jr., and Lester R. Dragstedt. *Arch. Surg.* 1947 55 114.

This article pertains to the treatment of patients with benign gastric ulcer by section of the vagus nerves. The rationale is based on the following considerations:

When the lesion is in the pyloric antrum and readily accessible it is probably treated best by a sub-

total gastrectomy however when the lesion is high on the lesser curvature close to the treatment of a resection extensive enough for the esophagus, a possible malignancy would involve a total gastrectomy. Total gastrectomy is much more hazardous than partial gastrectomy and the resulting digestive and nutritive defect constitutes a definite disadvantage. When these facts are taken into consideration, together with the small percentage of gastric cancers that can be cured by any type of surgical treatment, the authors believe a total gastrectomy is not justified in the absence of a total gastrectomy of malignant growth.

Of the authors group 250 cases of peptic ulcer treated by vagotomy 8 were cases of gastric ulcer. Among these were 3 in which there was a coexistent active duodenal ulcer. In such cases the possibility of malignant growth is generally believed to be about 1 per cent. Therefore when cases of combined gastric and duodenal ulcer are refractory to medical management, the authors believe that vagus section is indicated. In 3 such cases, healing took place extremely rapidly with no recurrence of symptoms. In 3 other patients in this series large chronic gastric ulcers were present high on the lesser curvature of the stomach. These were refractory to medical and x ray therapy. Subtotal gastrectomy as a method of treatment had been refused. In all 3 cases the ulcers healed promptly after vagus nerve section. All these patients remained well 1 year for more than 3 years and 1 for more than 3 years.

The 3 remaining patients in this series also had chronic gastric ulcers high on the lesser curvature but a differential diagnosis between benign gastric ulcer and carcinoma could not be made even with the aid of laboratory studies, roentgen examination and gastroscopic observation. Palpation and inspection of the lesion at laparotomy were also not decisive. A type of therapeutic test vagus nerve resection was done. Although there was complete symptomatic relief in both cases the ulcers failed to heal. Total gastrectomy was therefore advised.

The authors are of the opinion that unless the diagnosis of malignant growth is certain gastric ulcers high in the stomach should be treated by vagotomy. If the lesion is benign section of the vagus nerves may bring about prompt healing in cases that have proved resistant to intensive medical management. On the other hand if healing does not occur within a period of from 4 to 6 weeks the surgeon has additional evidence for the belief that the lesion is malignant and can undertake a total gastrectomy with a better conscience.

HAROLD LAUFMAN M D

Clinical Evaluation of Complications Observed after Transphrenic Vagotomy K. S. Grimson G. J. Baylin H. M. Taylor F. H. Heuser and R. W. Rundles. *Arch. Surg.* 1947 55 175

Fifty-seven patients with refractory or frequently recurring peptic ulcer were treated by transphrenic vagotomy or transphrenic vagotomy plus gastro-

enterotomy. The persistence in using the transphrenic approach is explained by the assumption that it minimizes the chance of incomplete operation or of regeneration. The result obtained by questionaire office visits and re-examination in the hospital indicated that of 56 surviving patients are completely satisfied 27 are almost completely satisfied and 7 are only partially satisfied while 1 was dissatisfied because of an exacerbation of a pre-existing gastrointestinal disturbance with vomiting and diarrhea. This patient died 2 years after vagotomy and gastroenterotomy due to rupture of the stomach after an acute gastric dilatation and terminal massive hemorrhage from a jejunal ulcer. The greatest difficulty has been occurrence of obstruction at the outlet of the stomach with retention of the gastric contents and dilatation. Obstruction is usually due to abnormal function of the outlet of the stomach after removal of vagal control. Obstruction and retention have necessitated secondary gastroenterotomy in 5 patients from 11 to 105 days after transphrenic vagotomy. Two other patients with serious symptoms as the result of retention are being treated with partial success by parasympathetic drugs.

Thirty-six patients were subjected to transphrenic vagotomy alone. Of these only 9 were completely satisfied with the results of the operation. Reasons for dissatisfaction consisted of vomiting during the first several months (3 cases), recurrent severe abdominal pain (3 cases), severe pain (3 cases), melena, a sensation of fullness after eating, 18 instances of foul eructations during the first 3 months with the persistence of these eructations in 10 patients. Of the 36 patients without gastroenterotomy 20 who had been previously constipated had normal bowel habits after vagotomy while 4 had moderate constipation. In 11 cases there was a continuous or periodical looseness of stools, and in 1 case a serious diarrhea.

Of 21 patients who had gastroenterotomy before, at the time of or after vagotomy 6 had marginal ulcers occurring after subtotal gastric resection 3 enterostomy after gastroenterotomy 3 gastroenterotomy just before vagotomy, 5 gastroenterotomy after vagotomy. Of these 20 patients only 12 were completely satisfied 5 almost completely satisfied 5 almost completely dissatisfied. Unexplained serious episodes of colicky pain occurred in 3 patients. One of them had a stomal ulcer and nonfunctioning gastroenterotomy 3 months after vagotomy. In 13 of these 20 patients there was a sensation of fullness after eating during the first 3 months after vagotomy and this persisted in 6. The author found that vagotomy may be of value when combined with gastroenterotomy or when employed for stomal ulcer. He does not believe that transphrenic vagotomy alone should be used as standard treatment.

HAROLD LAUFMAN M D

Partial Gastrectomy for Simple Ulcer. A. D. Watson. *Brit J Surg* 1947 34 353

A follow up study of 138 patients who had undergone partial gastrectomy for simple ulcer was carried out in an effort to determine whether the results justified the operation. In the course of this study some undesirable side effects of the Polya operation were seen which led to criticisms of this type of anastomosis. None of the patients had been operated upon less than 6 months previously. The results of the follow up are considered under the following headings: (1) clinical and functional result, especially in connection with the length of the loop and the width of the stoma; (2) the fractional test meal, with particular reference to the operation of pyloric exclusion; and (3) anemia.

The general impression gained from talking to these patients is that the operation of partial gastrectomy is definitely worth while, and this impression is confirmed by the statistics. The average period of convalescence after operation has been from 3 to 4 months. Most of the workers have returned to their original employment and have not lost time from it since. A number of the patients have failed to increase their weight to their preillness level but despite this, no increased liability to ill health was noticed. Only 3 patients had abnormal appetites, one being more, and the other less, hungry than normal. When interviewed, the majority were eating normally. The functional result or the present subjective state of the gastrointestinal tract, was as follows: excellent in 40 per cent, good in 43 per cent, improved in 11 per cent, and not improved in 3 per cent. In 23 per cent of the cases there was a recurrence.

The following features were common to the three cases of recurrence: the patients were all males; the original lesion was a duodenal ulcer; the anastomosis was full width and antecolic; and there was no x-ray or clinical evidence of afferent loop obstruction. These 3 cases support the common belief that duodenal ulcers are more likely to lead to recurrent ulceration and that free acid is only a predisposing factor to ulceration. All cases of recurrence were of the long loop antecolic type. The recurrence rate therefore was antecolic in 33 per cent (92 cases) and retrocolic in 0 per cent (34 cases). One other feature common to all 3 cases with recurrence was a wide stoma. X-ray examination and fractional test meal studies showed that the stomach remnant emptied readily and rapidly. This does not support the view that rapid emptying gives greater protection against recurrent ulceration because of the more rapid neutralization of acid.

There are 3 possible causes for the not uncommon postcibal syndrome of disagreeable sensations on taking food: (1) the small size of the stomach stump; (2) reflux into the afferent jejunal loop; and (3) "dumping" into the jejunum. The author does not consider distention of a small stomach stump or reflux into the afferent loop to be the cause of these symptoms for a number of reasons. In this series

only a few patients stated that their meals were of necessity of smaller volume than normal although many restricted the volume of food in order to lessen the postcibal symptoms. "Dumping" is the commonly accepted cause of most of the unpleasant symptoms after gastrectomy and the author suggests, as do many others, that a reconstruction of the Hofmeister Finsterer valve type might help to do away with some of the jejunal dumping by narrowing the entrance to the jejunum. He believes further that rapid emptying of the stomach due to the size of the anastomosis is responsible for the vomiting of bile in some of these patients.

In the course of this study 71 fractional test meals were carried out. Mucus was present in all specimens in all cases. Bile was present in all specimens in most of the cases. All of the patients showed a lowered total acidity, which indicated an actual diminution in the quantity of gastric juice secreted. The cases in which the test meals were done were divisible into two main groups: 49 in which the ulcer, whether gastric or duodenal, was removed completely and 22 in which the modern modification of pyloric exclusion for duodenal ulcer was performed. The 49 test meals after routine gastrectomy confirmed the usual findings, i.e. most of the cases failed to show the presence of free acid and all showed a diminished total acidity. Only 7 cases showed free acid. In 2 of these the patients had an excellent clinical result, in 4 a good result, and in 1 there was some improvement. The figures show that the stomach remnant does not appear to behave differently whether the ulcer was gastric or duodenal, although duodenal ulcer is usually associated with a much higher acidity. The length of time after operation would appear to make no difference to the acid secreting capabilities of these postoperation stomachs. The 22 test meals after gastrectomy with pyloric exclusion and closure of the antral mucosa showed that 14 of the patients had free acid. If one believes that recurrence of ulceration is at least associated with the presence of free hydrochloric acid, then one might expect that the incidence of recurrence in this group would be higher. Fortunately this seems not to be so although most of the cases are of fairly recent operation date. The presence of free acid is rather alarming and suggests that until we know more about the exact role of free acid in peptic ulceration, pyloric exclusion should not become a routine operation. The higher incidence of free acid in these cases may be due to incomplete removal of mucosa from the pyloric antrum, or possibly because the whole of the first part of the duodenum is preserved and continues to manufacture gastrin.

Hypochromic anemia is definitely a complication of partial gastrectomy but does not occur frequently enough for the operation to be condemned on that account. It is more common after gastric ulcer and is almost always of the microcytic type. It is usually of mild degree but may become severe if not treated. In either case response to iron is excellent. Diet for prolonged periods may be a predisposing factor but

the anemia is not related to the presence or absence of free acid. The anemia is insidious and often causes no complaints, and females are more prone to it than males. A preoperative anemia is not unreversible and the clinical result does not depend upon the blood picture. The possibility of anemia in a patient after a Polys gastrectomy for gastric ulcer should be borne in mind since it seems to be a disadvantage of that operation.

JOHN L. LUNDQUIST M.D.

Aberrant Gastroduodenal Pancreatic Tissue (*Les pancréas aberrants gastro-duodénaux*) R. Joyeux, H. L. Guilbert and Guerrier *J. chir. Par.*, 1947 63 261

The discovery at operation of aberrant pancreatic tissue is not infrequent and such tissue should no longer be considered an anatomical curiosity. The authors present the case histories of 3 patients in whom accessory pancreatic tissue was found in 1 patient on the duodenal bulb and in the other two on the wall of the pyloric antrum. The symptomatology closely resembled that of an ulcer and it was with the probable diagnosis of duodenal ulcer in 2 cases and of pyloric ulcer with stenosis in the other case that the patients were operated upon. Subtotal gastrectomy was done in each of the 3 cases.

A review of the literature presents one series of 33 patients exhibiting aberrant pancreatic tissue all of whom had symptoms which led eventually to surgical intervention. These as well as previous reports bear out the fact that accessory pancreatic tissue occurs most frequently in the stomach duodenum and jejunum. The aberrant tissue was found in the wall of the pyloric antrum or the duodenal bulb in 26 of the 33 patients, near the duodenojejunal angle in 2 in Meckel's diverticulum in 2 and in the gall bladder the ampulla of Vater and the rectal mucosa in 2 patients each. It is because of the predominant localization in the pyloroduodenal area that symptoms requiring surgical intervention may occur.

Anatomically the accessory pancreas may be represented as a small plaque, a small tumor or more often by a simple thickening of the wall of the digestive tract which often may cause ulceration of the mucosa. In the usual case the tumor is small and is located either in the submucosa or the muscularis where it separates the muscular fibers. Some of the aberrant tissue may merely rest upon the gastroduodenal wall. Histologically, in the great majority of cases the tissue contains both exocrine and endocrine elements. However in many cases the cells of the islands of Langerhans and the ductile elements may not only be atrophic, but the site of acute or chronic inflammation or of cystic degeneration.

The aberrant pancreas is physiologically active tissue. Many reports in the world literature associate accessory pancreatic tissue with the presence of gastroduodenal ulcer but in the author's experience this was an uncommon couplet. The mucosa is usually intact and it may be mere coincidence that an ulcer is found in contact with an accessory gland.

The symptoms may be merely functional. Dyspepsia is a common complaint. Symptoms of gastroduodenal ulcer with or without pyloric stenosis are frequent. Two factors in the operative diagnosis are important (1) the pancreatic nodule has neither the consistency of a neoplasm nor of an ulcer and (2) the serosa does not have the cicatricial appearance of serosa in contact with an ulcer.

The accessory pancreatic tissue results from the faulty fusion of the buds which embryologically form the pancreas. Some workers are of the opinion that the occurrence is a throwback to the lower animals the cyclostomes in which the pancreas is included in the intestinal wall.

When symptoms indicate laparotomy and suspicious nodulations are found in the upper intestinal tract excision of the nodule and immediate frozen section examination will determine the diagnosis in the majority of cases. Simple excision of the lesion is adequate in most cases but partial gastroduodenectomy may be necessary when a large amount of accessory pancreatic tissue is complicated or associated with peptic ulcer.

ORVILLE F. GRIMES, M.D.

Schwannomas of the Stomach (*Sur les schwannomes de l'estomac*) Jean Gomez. *J. chir. Par.*, 1947 63 463

The frequency with which schwannomas of the stomach occur as reported in the world literature varies between 0.5 and 1.5 per cent of all gastric tumors. The schwannoma (more familiarly known in the American literature as neurilemmoma or perineural fibroblastoma) is the second most common benign gastric tumor the myoma being the most common.

Various opinions have been expressed concerning the origin of these tumors. It is the belief of some that they arise from the endoneurium and are therefore of mesodermal origin. Others have indicated that they arise from the cells of Schwann and hence from ectodermal anlage.

The favorite sites are the pylorus and the cardia. Clinical symptoms arise from the mechanical interference occasioned by the presence of the tumor. These forms are described (1) an interstitial form in which the tumor is entirely intramural ovoid usually small seldom ulcerated and well limited by a connective tissue capsule (2) the endogastric or pedunculated form which may become quite large and is usually ulcerated and (3) the extragastric form arising from the serosa which may attain a large size and may displace the stomach considerably by its pressure.

Of especial interest is the usual existence of submucosal nodules separate from the principal tumor but having an identical histological picture. The tumors are extremely pleomorphic frequently assuming fibrosarcomatous or myosarcomatous aspects. Pseudocarcinoma or colloidocystic degeneration is common and it is for these reasons that the malignancy or benignancy of these tumors is many times in doubt.

Gastric hemorrhage occasionally of sufficient severity to cause an anemic state is the most common clinical finding. Vague dyspepsia is common.

Röntgenologically by the use of contrast media, the pedicle of the tumor can many times be shown this will indicate a benign process in most cases. The mobility of the lesion is the important clinical factor in distinguishing the benign lesions from cancerous growths.

One can entertain a presumptive diagnosis of a benign gastric tumor by the discovery of an epigastric mass with the preservation of a state of well being, gastric hemorrhage without pain, the existence of a hemorrhagic state without cachexia, and the absence of periodicity of the pain. These clinical findings plus the roentgenological findings of a perfectly delimited tumor with regular contours and an ulceration in the mass, and a gastroscopic appearance similar to that of a diverticulum may permit one to make a presumptive diagnosis of schwannoma.

If untreated these tumors may cause distress by compression of the neighboring organs hemorrhage infection obstruction at the pylorus, perforation or by malignant degeneration.

The treatment should always be surgical. Local excision of the lesion with a generous margin of the base is employed many times. However the authors believe that subtotal gastrectomy by which no less than two-thirds of the stomach is removed is the method of choice in order to remove the aberrant nodules which are usually present. A limited excision may be employed for the extragastric type.

The author briefly presents the case histories of 4 patients in whom subtotal gastrectomy was performed to remove endogastric schwannomas. All have remained well. OVERTON F. GRIGGS, M.D.

Gastric Cancer Owen H. Wangersteen. *J Am M Ass* 1947 34 216

This extensive review of the problem of gastric cancer deals with the disease from the standpoint of etiology, diagnosis, and treatment. It is of especial interest, since it combines scientific data with philosophic thinking, and a delineation of the problems facing us at present and in the future.

The ultimate salvage of life following a diagnosis of gastric cancer is small. Though gastric cancer is curable the disease is rarely recognized in time for such a cure to be accomplished. Cancer of the stomach is the most frequent of all malignant growths.

From the standpoint of etiology there is a wide diversity of opinion concerning the origin of gastric cancer. Most authorities agree that gastric cancer probably does not originate *de novo* from a normal gastric mucous membrane. There is no unanimity of opinion, however, concerning the importance of items which it is believed may give special encouragement to the development of gastric cancer among these are to be enumerated (1) the benign polyp, (2) gastritis, and (3) gastric ulcer.

There is also a sharp difference of opinion in regard to the role of extrinsic factors in the origin of

gastric cancer in man. There are those who believe that the so-called constitutional susceptibility is important. Nettlehip included such extrinsic factors as diet, age, heredity, heat, alcohol, bacteria, viruses, allergy, and infections. A study carried out in the author's clinic indicated that approximately 30 per cent of families give a history of cancer suffered among their members, but there was no closer correlation than this.

Several well known surgeons who, in the estimation of their colleagues, were authorities on the clinical aspects of the disease and who essayed to instruct others in the early manifestations of gastric cancer recognized the signs of the disease in themselves too late to benefit by that therapeutic agent of which they themselves were masters. Among them are to be enumerated the names of Johannes von Mikulicz, W. J. Mayo, D. P. D. Wilkie, and Martin Kirschner. R. D. Carman, a well known roentgenologist who contributed a useful sign to the roentgenologic diagnosis of gastric cancer had a gastric cancer which was inoperable before he recognized the signs of the disease in himself.

In an attempt to find precursors of gastric cancer, an experiment was undertaken to scrutinize carefully all patients with demonstrated histamine achlorhydria in men over 55 and in women over 65 years of age. Among 464 patients who were achlorhydric to histamine, 15 patients with polyps were found—the most fruitful observations of the study. During the 15 month period that this study was under way only 3 undetected gastric carcinomas were uncovered. Only 1 of these, however, was early. This patient's lesion was missed by roentgen examination. At operation it was found that he not only had a gastric carcinoma but also a second primary lesion of the cecum.

The experience of this clinic suggests that radical operations for gastric cancer including total gastrectomy can be performed at a reasonable risk. For the past 4 years, during which time 160 resections (including total gastrectomies) were performed, the hospital mortality was 8.1 per cent. In 1945 there were 62 resections (including 9 total gastrectomies) with 3 deaths (4.8 per cent mortality). The resection rate of patients operated upon for gastric cancer in this clinic was approximately 90 per cent. This implies that palliative resections were undertaken in a number of instances.

Cancers *in situ* perhaps will not often be recognized in the stomach yet periodic examination of all men and women who have reached the cancer years undoubtedly will make an important contribution to the earlier recognition of cancer. One cannot await the complete evolution of the clinical symptoms.

The establishment of cancer detection clinics, staffed by specialists, affords the best promise of the early recognition of cancer. Women over 40 and men past 50 years of age should report regularly to such clinics. The solution of a difficult problem such as this demands the following: (1) members of the

medical profession must look at the problem realistically and learn to know all the facts bearing on it. (2) they must constantly enlarge their knowledge of the field by vigorous research and clinical investigation. (3) all available resources must be combined to lead pursuit of the inquiry the greatest promise of solution. (4) the solution of the problem must envisage an interest in the problem as it relates to the present generation as well as to those yet unborn. New discoveries as well as to those yet unborn. energetic research program constitute the hope of the future.

HAROLD LAURMAN, M.D.

A Statistical Study of 1,405 Cases of Cancer of the Stomach. W. L. Harnett. *Brit J Surg* 1947 34: 379.

This study is based on the statistical survey of 1,405 cases of primary carcinoma of the stomach published by the British Empire Cancer Campaign in 1934. The cases were followed up for 5 years with only 1 per cent of the patients being untraced.

There were 856 males (61.7 per cent of all male cases of cancer registered) and 549 females (69 per cent of all female cases). The region of the stomach postmortem findings. Fifty-four per cent of the carcinomas were in the pyloric region, 33 per cent in the cardia, 13 per cent in the pyloric region, and 13 per cent in the cardia.

The youngest patients were a female aged 30 and a male aged 31. The mean age of the 691 patients who were submitted to operation was 56.83 years.

The occupations of the male patients were arranged in order of frequency and compared with the percentage of males over 14 years in Greater London following the same occupations. The figures warranted the conclusion that those admitted were a fair sample of the general population and thus there was no connection between the occurrence of gastric carcinoma and any of the occupations.

Definite pain following eating was the first symptom in 74.7 per cent of all the patients. Sudden onset with the vomiting of blood occurred in 15 per cent of the entire group and in 35 per cent of those with growths in the cardiac region. In 66 per cent there were no symptoms directly related to the stomach and the diagnosis was established by surgery or autopsy. In 13 per cent, metastases to the bones, lungs or the lymph nodes preceded discovery of the primary tumor. Onset of the symptoms was stated to be gradual in 68.4 per cent and sudden in 31.6 per cent.

Fifty-four and one half per cent of all the patients consulted a doctor within the first 3 months and 10 per cent within the next 3 months. There was some delay on the part of the physicians to treat the patients. Sixteen per cent came to the hospital directly 37 per cent were referred to the hospital for investigation at once, and 13 per cent after an interval of less than 3 months. 19 per cent were treated symptomatically for more than 3 months and 1 per cent were not at all worried.

Seventeen and one-half per cent of the patients lost up to 28 pounds in weight and 19.4 per cent lost more than 28 pounds. Only 3.8 per cent lost no weight at all and the amount lost in the other cases is not known. There was a definite palpable tumor in 49 per cent of the patients and an indefinite mass in 9 per cent. Obstruction to the passage of food was diagnosed clinically in 33.6 per cent of the growths in the pyloric region, in 10 per cent of those in the mid gastric region and in 7 per cent of those in the cardia. Recognizable distant metastases were present in 35.5 per cent of all the patients on admission to the hospital. In 6.9 per cent the cervical or supraclavicular lymph nodes were affected, and in 5.4 per cent metastases could be palpated on rectal examination. Of 457 recognizable metastases, 85.3 per cent were in the liver or abdominal organs, 3.5 per cent were in the lungs and 3.6 per cent in the bones.

The 1,405 patients diagnosed as having gastric carcinoma were treated as follows: 687 had neither surgery nor radiotherapy, 33 were treated with radiotherapy, 243 had their stomachs resected, 215 had a palliative procedure, and 433 were explored only. The operative mortality for all radical operations averaged 39.9 per cent, ranging from 25.4 per cent for the Polya method of partial gastrectomy to 90 per cent for total gastrectomy. The 5 year survival rate for males for all radical operations was 19.8 per cent, and for females 27.1 per cent, not including the operative mortality. The 5 year survival rate for males for all methods of resection was 18.6 per cent and for females 19.8 per cent, not including the operative mortality.

There were 56 patients surviving after 5 years (4.03 per cent of all cases). Of these, 36 had been treated by partial gastrectomy, 7 by palliative operations, 2 by radiotherapy, 1 had exploration only and 10 had not been treated. The proper diagnosis of the latter 10 has since been questioned.

DANIEL RUCK, M.D.

Irradiation of Gastric Cancer. G. Cranston Fairchild and Alan Shorter. *Brit J Surg* 1947 34: 243.

Cancer of the stomach still remains a problem. It is responsible for 15,000 deaths annually in Great Britain, and for 40,000 in the United States, 33 per cent of all cancer deaths in America. It is the commonest type of cancer with the poorest results from treatment, for on the average, only from 1 to 4 per cent of all patients are alive after 5 years following curative surgery and only about 4 months following palliative surgery. At present some 80 per cent of patients with gastric cancer are beyond any hope of cure by surgery alone when first brought to the surgeon. But what if irradiation—so postmortem findings show that over 50 per cent of people dying of gastric cancer have the disease still confined to the stomach and immediately adjacent lymph glands. Because of the impossibility of a surgical cure in such a vast number of cases many other forms of treatment, including irradiation have been tried, but without striking success.

Different forms and combinations of irradiation applied to this vascus have their limitations and shortcomings. External irradiation fails because of the deep situation of the gastric tumour and its close relation to other vital organs—both factors tending to prevent adequate tumor dosage—and because of the high but variable radioresistance of gastric cancer cells, possibly increased by infection. Movements of the tumor make accurate centering of the x ray beam at repeated exposures difficult to obtain. Contact therapy with the Chaoul tube covers a relatively small area (2 cm. in diameter) in each field with very little penetration at low voltage. With the Chaoul tube, bulky tumors could not be destroyed by single surface doses at one operation, but needed repeated exposures. This could be done only through some kind of fistula or pouch formation. With such a small field as 2 cm., repeated applications would be required for most inoperable tumors, with the obvious difficulty of adequate and uniform dosage. Also such localized irradiation would have no appreciable effect on any glandular or other local spread the presence of which is the usual reason for inoperability. Radon seed implantation has the same difficulty of uniform and adequate dosage (as shown by subsequent radiography) when introduced at operation from either serous or mucous surface, or through a gastrostomy opening or the esophagoscope. There are also dangers of hemorrhage and infection and perhaps perforation due to massive necrosis of the tumor while the adjacent field of spread does not receive adequate irradiation.

Intracavity irradiation with the five way tube described by Livingston and Pack (1941) has, they claim, the advantages of easy application, fractionation of doses, avoidance of damage to adjacent vital organs, freedom from dangers of hemorrhage, infection, and perforation, and no interference with food intake, but they had not at that time determined how effective a total dose patients would stand, the most effective fractions into which to divide the total dose, or the results as regards palliation or cure. Used alone it would appear not to have much effect on local spread, but combined with direct irradiation it might perhaps be used to supplement the dose reaching the center of large gastric tumors. Many people think that irradiation not only shortens the patient's life but also adds to his sufferings, and therefore is quite unjustifiable. While this may be true of many of the other methods of treatment, direct irradiation at high intensity has none of these disadvantages.

Fairchild (1933) first conceived the idea of direct irradiation of deep-seated tumors exposed temporarily at operation. The following advantages of the method are noted.

1. More accurate information about the size, shape, position, and extent of the primary lesion and any local or general spread, can be obtained at the exploratory operation than can be found out by any other methods, either clinical or laboratory. In the thorax, where a fairly satisfactory radiological examination can usually be made the extent of a

cancer is almost invariably greater than it seems from x ray films. So, in the abdomen, the growth is nearly always more extensive than can be determined by the usual examinations and investigations. According to Walters et al. (1942) exploratory operation is the only reliable way of deciding the correct form of treatment.

2. Biopsy specimens can usually be obtained to help confirm the diagnosis. With palpable glandular involvement this can be done safely, but incision of the tumor may spread tumor cells or lead to perforation owing to subsequent massive irradiation. This biopsy may not be practicable in all cases, but desirable to see and feel the tumor should make the diagnosis more certain than when relying on external methods of examination alone.

3. A more accurate and effective dose of irradiation at high intensity can be given direct to the tumor and field of local spread without irradiating such a large volume of normal tissue including vital organs and skin, unavoidable when irradiating from the skin surface. This may be of great importance in an already anemic and cachectic patient.

4. More accurate centering of the x ray beam is possible under direct vision than when relying on x ray films or clinical examination alone.

5. The skin is left practically intact, and will permit further full dosage to be given externally at a later date should this be deemed necessary. Supplementary external irradiation was given later in some of the earlier cases, beginning about 10 days after operation as it was believed the initial dose was too small to cure. Some patients had further external irradiation after some months.

6. Various operations to relieve obstruction can be performed before the irradiation, at the same or an earlier and less extensive laparotomy such as gastrostomy for cardiac obstruction and gastrojejunostomy for pyloric lesions. Though the obstruction may not be severe it increases owing to fibrosis of the tumor after irradiation. In hopeless cases these operations can be done without irradiation to relieve symptoms.

Diagnosis and localization of the tumor are achieved as accurately as possible by clinical, radiological, gastroscopic, esophagoscopic, and laboratory investigations. The general condition of the patient is investigated as regards the possibility of metastases, state of nutrition, and fitness for anesthesia and operation.

Owing to the tendency of the growth to spread along the stomach, or to lymphatics above, behind, or below the stomach, the exposure must be such as to enable the direct irradiation to be carried out in an anteroposterior plane otherwise uniform irradiation of the tumor area would not be possible. It follows that the left transthoracic approach is unsuitable for direct irradiation even for the cardiac area and lower esophagus. This may be in one or two stages (Fairchild and Shorter 1945).

1. When there is well marked cardiac or pyloric obstruction gastrostomy gastrojejunostomy or even

Jejunostomy may be necessary before the patient's condition can be improved sufficiently to stand the wider exposure and irradiation. This is usually done through a small upper left paramedian incision making exploration of the tumor and the whole abdomen possible. Many cases have in this way been found unsuitable for irradiation owing to unsuspected wide spread metastases.

2 When the patient's condition seems satisfactory the abdomen is explored through a different incision more suitable for extension, even into the thorax if necessary. This practice has been followed when the condition of the patient will allow it so as to avoid the two operations advocated by Garlock. Also it saves moving the patient in making separate incisions for the exploration and the main exposure. The form of treatment and the main exposure in decided upon beforehand to be carried out complete in abdomen must be thoroughly explored before making an extensive exposure especially before opening the thorax. It would seem to be unwise and unfair to the patient to open his thorax and divide his diaphragm before estimating carefully the extent of spread in the abdomen.

When operations to relieve obstruction are necessary they are done before the irradiation is commenced. Irradiation of the stomach and when the field is avoided by displacement and packing out protect the skin edges of the wound. More recently a special sterilized applicator was used to avoid infection during irradiation but allows accurate visualization of the tumor in the x-ray beam. To avoid shock produced by frequent moving a special trolley has been designed on which the patient can have both the operation and the irradiation.

Fifteen patients were treated by direct irradiation. These cases can be divided into two groups. In the first group were 7 cases in which the irradiation was purely palliative owing to obvious spread beyond the possible field of irradiation, or to a poor general condition. Of these, 2 patients are alive and well after 5 weeks. 1 lived 6 months. 1 lived 5 months and 2 lived 4 months. The rest died sooner. In the second group of 8 cases the growth appeared to be limited to an area that could be irradiated. Of these, 2 patients lived 24 months and 1 lived 3 months after treatment. The remaining 2 patients died within the first week—one from bilateral pulmonary collapse while the wound was being closed, the other from spontaneous pneumothorax on the opposite side 4 days after operation.

Although the series is small, direct irradiation with high intensity will prove to be a rational and hopeful advance in the treatment of cancer of the stomach and other viscera. Whether the cancer is rendered inoperable by the poor general condition of the patient or by irretrievable local spread this method will

often succeed where surgery alone must inevitably fail. Though wider exposure is needed than for surgery alone, with adequate precautions the whole procedure should not be so shock-producing as is wide surgical excision.

Exploratory operation is the only reliable way of deciding the correct form of treatment, and the hospital of the future will have a radiotherapy room adjoining the operation theater to facilitate direct irradiation.

Performed Sigmoiditis (Sigmoiditis perforata) Adol
fo Duforich and S Form. *Brazil med cir* 1946
8 237

The authors present the case of a patient with perforated sigmoiditis who was operated on 6 hours after the perforation. In this case it was not possible to identify the etiologic agent although other authors found the majority of cases to be the causative factor in

A relatively large ulceration of the mucosa and submucosa was encountered with an abundant infiltration of leukocytes as well as an increased number of histiocytes and of other elements not well identified. The symptomatology was similar to that of an acute perforated appendicitis. Pain, usually in the left lower hypogastric area was sudden in onset and unbearable. The patient was in a cold perspiration and a prodromal ulcer and it produced a certain amount of shock. The patient was in a cold perspiration and fainted at the height of the paroxysm. At the onset of the peritonitis the pulse and temperature were parallel. Tenderness was elicited on the side of the perforation associated with muscular rigidity which was more prevalent on the left side. Abdominal distention came later. Vomiting was not early or frequent although nausea was present from the start.

This condition must be differentiated from the acute appendicitis perforated gastric and duodenal ulcers. The prognosis depends on early surgical intervention, virulence of the micro-organisms and the lesions of the peritoneum to form protective adhesions. The author's policy was discharged in 72 days after admittance.

The treatment was simply surgical and consisted of suture of the defect in 3 planes and covering of the site of perforation with epiploicæ. Sula therapy with drainage of the peritoneal cavity is of unquestionable value.

A Case of Multiple Hyperplastic Tuberculosis of the Colon. *Harald Brodin Acta radiol., Stockh.* 1947 28 237

Hyperplastic tuberculosis of the intestine is as a rule a solitary tumor most often located at the ileocecal valve. It is an uncommon condition. In the literature one series of 72 cecal tumors is reported, 9 of which were tuberculous and of the only 5 were of the hyperplastic form. Another report of 8 cecal autopsies showed 233 cases of intestinal tuberculosis of which 2 were of the hyperplastic

type. Cases in which multiple hyperplastic tuberculous lesions of the intestinal tract are present are rare.

In patients suffering from this disease other foci of tuberculosis are uncommon. Some authors believe this form of tuberculous infection is a primary type of infection. The mode of infection is thought to be via the blood stream, although it may originate by lymphatic spread from tuberculous mesenteric glands.

The symptoms of hyperplastic tuberculous infection of the colon are usually of long duration and consist of colicky pain, loss of weight, nausea and anorexia. Diarrhea, constipation, or alternating periods of each may be present. Examination usually reveals a palpable abdominal tumor, anemia, slight rise in temperature and a raised sedimentation rate. Fistulas may be present. The diagnosis is difficult, and the differentiation from cancer may be impossible. Multiple cancer of the colon is more common than multiple hyperplastic tubercular tumors. A case of multiple hyperplastic tubercular tumors of the colon is presented.

F J LEREMARK, JR. M.D.

The Management of Cancer of the Colon. Paul L. Hoxworth and James Mithoefer. *Surgery* 947 ss 572

The present differences of opinion among surgeons with respect to operative procedures for cancer of the colon lie largely in the technique of resection and re-establishment of continuity of the bowel after resection. Two schools of thought exist—one chooses a method requiring delayed anastomosis and the other prefers to restore continuity of the intestine immediately. Much progress has been made along both lines of approach since cure of cancer of the colon was first undertaken. At the authors' clinic the plan of choice has been that of anastomosis at the time of resection by either an open or closed method. For the success of this procedure it is necessary to establish suitable conditions for the relief of obstruction for the avoidance of sepsis and for primary healing by use of careful preoperative, operative and post-operative measures. If these conditions cannot be met in each individual case it is safer to resort to exteriorization and delayed anastomosis. Under this plan 87 resections for cancer of the colon were performed in the 9 year period from 1938 to 1946. The management is presented in some detail and the operative results are reported.

Emphasis is placed upon the following fundamental principles:

In the preparation of the patient for resection relief of obstruction and thorough cleansing of the intestine should be achieved along with preliminary correction of anemia and of disturbances in electrolyte nutrition and hydration. Operative principles include the use of the transverse abdominal incision, careful attention during resection of the mesentery or preservation of the blood supply to the segments of bowel at and adjacent to the proposed site of anas-

tomosis, gentleness in the dissection and handling of the bowel and its mesentery, adequate mobilization of the segments to be anastomosed in order to prevent tension at the line of suture, precision in the placing of sutures after careful preparation of the bowel to receive them, the use of inverting mattress sutures which catch the submucosa but do not penetrate the mucosa and are tied tightly enough to hold serosal surfaces in apposition without strangulation of the tissue, avoidance of inverting too much of a diaphragm, accuracy in approximating the edges of the mesentery and in re-peritonealizing denuded areas, isolation of the field of resection and exclusion of contaminated gauze, instruments, towels, and gloves from the field before re-peritonealization and closure of the wound.

Further principles include the use of continuous gastric aspiration until obstruction is relieved, and, during the immediate preoperative and postoperative period, the provision of adequate hydration and nutrition, the prevention of atelectasis after operation and parenteral administration of sulfadiazine and penicillin if soiling has occurred or at the onset of signs of sepsis.

The 87 cases represent an operability rate of 60.4 per cent among a total of 144 cases. Of the 87 resections performed, 16 were classed as palliative. In lesions of the right colon ileotransverse colostomy was carried out as the first procedure in 13 cases, 10 of which it was only palliative and was not followed by resection. Only 3 of the 24 patients with cancer of the right colon who had resection showed obstruction, whereas about half of those with tumors of the transverse and left colon had complete or partial obstruction at the time of admission to the hospital. In all of these cecostomy or transverse colostomy was done as a preliminary step to relieve obstruction. In 6 of 63 cases in which resection was done for lesions beyond the hepatic flexure circumstances encountered at the time of resection prevented the operator from proceeding with end-to-end anastomosis.

Among the 87 cases of resection there were 6 deaths, a mortality rate of 6.9 per cent. Four deaths were due to leakage at the site of the anastomosis which resulted in peritonitis. All of these cancers were in the left colon. One patient died of pneumonia and 1 of uremia. The average hospital period for the 79 surviving patients treated by resection and immediate anastomosis was 36 days from the time of resection to time of discharge from the hospital. In patients in whom a cecostomy was performed the average interval between the cecostomy and resection was 15 days.

JOHN L. LUNDQUIST M.D.

The Management of Carcinoma in the Several Parts of the Colon. William F. MacFee. *Ann. Surg.* 1947 125:1-5.

The author describes the historical development of the modern techniques used in surgical therapy of carcinoma of the colon. He cites the perfection of an aseptic method of resection and anastomosis, pro-

SURGERY OF THE ABDOMEN

imal decompression in the presence of the obstructed use of intestinal antiseptics, earlier diagnosis and greater appreciation of the importance of fluid and proteio balance, and the use of vitamins and blood transfusion as factors in lowering the mortality resulting from the surgical treatment of carcinoma of the colon.

The various proponents of the exteriorizing stage resections and those advising primary resection with end-to-end anastomosis are named. The author states that the present trend is in favor of resection with end-to-end anastomosis and justifies this by stating the fact that in the numerous series of case reports, the mortality of primary resection with anastomosis is half that of exteriorization with stage resection.

Reichel's basic principles for closed resection with anastomosis are reiterated: (1) the general condition of the patient must be adequate for a long operation; (2) the proximal bowel must be decompressed; (3) the intestine must be viable and free of circulatory disturbance, and there must be no tension on the sutured lines of the anastomosis. In the absence of obstruction fixation or infection a carcinoma in almost any part of the colon may be resected and continuity restored immediately without undue risk.

Uncomplicated carcinoma of the cecum ascending colon and hepatic flexure may be resected and ileo-transverse colostomy performed at a single operation. In the presence of obstruction fixation or infection ileo-transverse colostomy should be done first with resection following later.

Carcinoma of the transverse colon ordinarily may be resected and anastomosis established as a one stage operation. Obstruction extensive fixation or infection calls for preliminary colostomy or coloproctostomy. Carcinoma of the splenic flexure is often recognized late, complications are frequent and surgical approach may be difficult. Preliminary colostomy or transverse colostomy should be the rule with primary one stage resection reserved for the exceptional case. Transverse or subcostal incision provides a good exposure.

In the descending and sigmoid colon primary resection and immediate anastomosis are permissible provided there are no complications. Obstruction by colostomy or gross infection requires proximal drainage the latter. Diverticulosis may confuse the diagnosis.

At the rectosigmoid level preliminary transverse colostomy with complete diversion of the feces is a prerequisite for resection with immediate anastomosis. Faulty healing of the suture line frequently results in leakage infection and fistulas. The presence of feces in such a field is a serious disadvantage drained through the pelvic peritoneal floor should be freely drained through the coccygeal bed. Primary one stage resection and anastomosis may succeed in any part of the colon proper but it should not be performed for tumors in the rectosigmoid and its use

elsewhere should be restricted to uncomplicated lesions.

 LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Traumatic Rupture of the Liver without Penetrating Wounds: A Study of 32 Cases. Louis T. Wright, Aaron Prigot and Lyndon M. Hill, Jr. Arch. Surg. 1947 54: 613

This article is a report of 32 cases of traumatic rupture of the liver without penetrating wounds studied at the Harlem Hospital between 1935 and 1946.

Of some 20,000 patients admitted to the Traumatic Service 18 had subcutaneous rupture of the liver an incidence of 1 to 1,121. In the present series there were 27 cases among 34,000 admissions an incidence of 1 to 1,259. These figures tend to show that this condition is not as infrequent as the reports to the literature would lead one to believe.

The liver and spleen together make up 75 per cent of all intra-abdominal injuries of solid viscera, with a somewhat greater frequency of solid viscera, with being struck by an automobile and falling are the more common causes of liver injuries occurred in males and 11 in females. The friability and position of the liver combine to render it vulnerable to direct injury and injury by contrecoup. The larger less protected right lobe is more easily injured. It was injured in 27 cases the left lobe was injured in 2 and both lobes were injured in 3 cases.

The liver when injured tends to split and crack in stellate fashion with hemorrhage and escape of bile. The dome of the liver was most susceptible which tended to disprove the idea that most ruptures occur along the posterior inferior surface where the liver is thrown against the vertebral column.

In all cases there were moderate (from 200 to 500 c.c.) or larger amounts of blood in the peritoneal cavity. The reasons for this copious hemorrhage are that (1) thin walled hepatic veins have no valves and do not retract or contract (2) blood mixed with bile does not clot readily (3) diaphragmatic movements aggravate the injury and (4) the friable hepatic tissue does not act as a tampon.

More trauma is necessary to rupture the liver than the spleen. In only 10 cases were there no associated lacerations of the brain and spinal cord ruptured spleen and fractures.

In classifying traumatic rupture of the liver the authors favor a classification dependent on the rate of hemorrhage. This rate may not be in proportion to the amount of damage to the liver. In a series of 21 cases reported by Vance one third of the patients died at the site of the injury, 38 per cent died within 6 hours, and 28 per cent lived long enough for clinical study.

The authors 4 clinical types are (1) massive hemorrhage causing almost immediate or sudden

death (2) acute hemorrhage producing shortly after injury a state of shock which rapidly becomes deeper (3) repeated small hemorrhages, and (4) spontaneous cure. Case histories illustrating each type are given. The greatest number of cases fall in the second and third groups.

The diagnosis of rupture of the liver is difficult even without complications. Symptoms may not develop for 6 hours or more. The signs are hemorrhage, shock, and peritoneal and diaphragmatic irritation. Rarely a tender mass may be palpable or blood appears in the vomitus.

Severe abdominal pain made worse with respiration is the most common complaint. Pain radiating to the right or left shoulder (Kehr's sign) is helpful if present, but frequently it is absent. Vomiting occurs not infrequently as a reaction to the trauma. Symptoms of internal concealed hemorrhage are present.

These cases usually show signs of shock. Bradycardia is not observed. The point of maximum tenderness is apt to be misleading in localizing the lesion. Rigidity and rebound tenderness may be present. A palpable abdominal mass is helpful when present. Jaundice is rare but may appear in from 48 to 72 hours after injury.

Repeated blood counts and hematocrit determinations are necessary until the diagnosis of intra-abdominal injury is established. If blood is found in the urine, it is wise to rule out other causes of concealed hemorrhage.

X-rays may show a high diaphragm on the right in rupture of the liver. Abdominal tap and peritoneoscopy are invaluable aids in diagnosis of rupture of the abdominal viscera. The abdominal tap performed in all 4 quadrants should always be used in any suspected case. It was used in 15 cases and failed to disclose blood in 3. The finding of blood is indicative of intra-abdominal injury, whereas failure to find it does not rule out intra-abdominal injury. No "false positive" results were obtained. Peritoneoscopy was used once with a positive result.

Nonurgical conditions, such as contusion of the abdominal wall or fracture of ribs with shock due to hemorrhage into cavities other than the peritoneum, must be excluded.

The treatment of this emergency is surgical and delay increases the operative risk. Conservative treatment has a mortality between 75 and 95 per cent. Preoperatively shock must be combated with blood and plasma. Preoperative enemas and spinal anesthesia are to be avoided. The authors do not use autotransfusion because the blood may be mixed with bile and it may contain toxic products from autolysis of liver tissue.

All cases of suspected liver injury should be explored as bile may be spilled into the abdomen and lead to bile peritonitis, necrotic pieces of liver tissue may be present, or hemorrhage may be uncontrolled. This exploration should be carried out as soon as the diagnosis is made, and supporting measures can be carried out simultaneously. Early operation tends to

eliminate complications such as infection and fatty and hepatic tissue embolism.

Bleeding may be controlled by steam cautery, compression clamps, large sutures with bone plates or omental and fascial strips, digital compression of the hepatic artery or suture of the liver to the abdominal wall. Various types of gauze packs or muscle, omentum, fat, or rubber dams have been used. Simple tears can safely be sutured. Recent work with gelatin sponge indicates that it may be the best method of repair as it reduces operating time, loss of blood, and mortality rates.

The prognosis for rupture of the liver depends on the severity of the rupture but also on the severity of the associated lesions. Only 6 of the 32 patients in this series lived—a mortality of 81.3 per cent. Of the 26 who died, 11 died within 4 hours without surgical intervention. Of the 15 operated on, 9 died—an operative mortality of 60 per cent. Of the 6 who lived there were only 2 with associated injuries. In all cases the rupture of the liver was packed with gauze. The only complications were purulent discharge from around the packing and a decubitus ulcer in 1 case. No instances of hepatorenal syndrome or liver death were encountered. In the recovered patients the morbidity varied from 16 to 98 days. The gauze packing was removed between the fourteenth and fortieth days.

ROBERT R. BROOKS, M.D.

Congenital Absence of the Gall Bladder. Earl O. Latimer, F. L. Mendes, Jr. and W. J. Hight. *Ann. Surg.* 1947, 25, 39.

Three cases of congenital absence of the gall bladder discovered at operation are presented. In 2 of these cases a cholangiogram made postoperatively by means of a T-tube, showed the common duct to be patent but revealed no evidence of structures resembling either the cystic duct or the gall bladder. Oral cholecystography also failed to show evidence of an intrahepatic gall bladder. An analysis of 71 cases of congenital absence of the gall bladder approximately half of which were found at operation and half at autopsy is tabulated with respect to age and sex, symptoms, preoperative diagnosis, and attempts to prove the presence of an intrahepatic gall bladder. Syphilis, catarrhal inflammation of the biliary tract, fetal peritonitis, maternal toxins, and mechanical factors have been advanced by various authors as the causes of this anomaly. A more easily defended theory involves the embryology of the biliary tree.

There is no group of symptoms or signs which is of value in making the diagnosis preoperatively. When cholecystography fails to produce any shadow whatsoever, congenital absence of the gall bladder is not suspected because of its rarity. There is no reported case in which the diagnosis was made before operation or autopsy. Should surgical procedure fail to reveal the gall bladder in or about its normal location, the presence of an intrahepatic gall bladder should be ruled out preferably by retrograde cholangiography.

JOHN L. LUNDQUIST, M.D.

The Diagnosis of Pancreatic Disease by Enzyme Tests Lester M. Morrison *J Lab Clin M., 1947 32 1107*

The clinician has long found the diagnosis and treatment of diseases of the pancreas to be most difficult and uncertain.

The 20 patients with organic disease listed included 3 patients with carcinoma of the pancreas, 2 with pancreatic cirrhosis, 3 with cirrhosis of the liver, 3 with duodenal ulcer and 1 each with gastric ulcer, infectious hepatitis and cholangitis, carcinoma of the pyloric end of the stomach, carcinoma of the gall bladder and bile ducts and nontropical sprue respectively.

The respective average readings in the normal controls and the "functional" cases appear to be clearly defined. However the difference between the average readings of the "functional" and those of the "organic" diseases seems small. This lack of contrast appears to be due to the inclusion of a group of cases under organic causes in which the pancreas itself was not primarily involved. Cases of gastric and duodenal ulcer or cholelithiasis are examples. On the other hand, when the cases in which the pancreas is involved primarily, such as by carcinoma or cirrhosis or by stone, are examined, the test readings are consistently zero or very close to zero.

Percentages were not calculated since the range of variation in normal subjects, patients with organic disease of the upper digestive tract and patients with functional diseases of the upper digestive tract were so great that only repeated zero or near zero readings were of diagnostic significance.

Over 1,000 pancreatic enzyme tests were made of the duodenal secretions in a group of normal subjects, in a group of patients with "functional" or nonorganic disease of the upper digestive tract and in a group of patients with organic disease of the pancreas, biliary tract, stomach, or duodenum.

The range and mean of duodenal pancreatic enzyme tests for normal subjects and patients suffering from upper digestive tract disorders are described. Variations of test findings are very wide in both normal subjects and patients with most organic diseases of the pancreas or upper digestive tract.

Normal subjects as well as patients with extensive and severe pathologic involvement of the pancreas such as cancer may give zero or near zero test readings in individual duodenal pancreatic enzyme tests.

In patients with organic disease of the stomach or biliary tract, pancreatic duodenal enzyme tests revealed no individual distinctive or diagnostic findings. However, their group mean value was definitely lower than the comparable value in normal subjects.

A group of 10 patients with chronic low grade or moderate inflammation of the pancreas, as revealed at operation, underwent a series of duodenal pancreatic enzyme tests performed before and after operation. The duodenal enzyme study failed to show any consistently abnormal findings of diagnostic value either preoperatively or postoperatively.

In 6 cases of extensive involvement of the pancreas by cancer or cirrhosis with pancreatic lithiasis, 125 tests gave abnormal findings in the duodenal pancreatic enzyme tests. These abnormal findings showed either zero or near zero values.

If a zero reading was found in the pancreatic enzyme tests of a normal subject, it was not consistently found at subsequent determinations. In the presence of advanced and extensive pancreatic disease such as cancer or cirrhosis, zero and near zero readings were found consistently at all subsequent determinations.

Extensive and advanced disease of the pancreas such as cancer or cirrhosis with lithiasis gave repeated zero or near zero readings in the duodenal pancreatic enzyme tests. Pancreatic enzyme tests are useful in diagnosing advanced and extensive disease of the pancreas. HARRY W. FINE, MD

On Subcutaneous Injuries of the Pancreas V. Taitainen. *Ann Chir Gyn Fenn 1947 36 62*

Because of the anatomic location of the pancreas, traumatic injuries of this organ are rare. Only about 100 cases were collected from the literature by one author in 1941. In a series of 9,500 autopsies in Finland, pancreatic injury was noted twice.

The symptoms of injury to the pancreas are not typical and depend on the nature of the injury. If there is serious damage involving the blood vessels and pancreatic ducts, immediate pain and increasing signs of peritoneal irritation necessitating prompt operation are present. Generally, blood and pancreatic discharge enter the omental bursa which results in violent symptoms of shock. The foramen of Winslow usually closes but it may remain open and allow contamination of the general abdominal cavity to occur. Frequently there is a delay of some 3 hours between the time of the accident and the development of symptoms, and, although a similar symptom-free interval occurs with rupture of other abdominal organs, some workers have considered this symptom-free period to be pathognomonic of pancreatic damage.

A fairly frequent complication of pancreatic rupture is the subsequent development of a pseudocyst; perhaps one fourth of all pancreatic cysts are of this type. Such pseudocysts usually arise in the lesser omental sac, and are developed in a few weeks or months following the accident. The cyst wall is made up of a thin connective tissue capsule; there are no epithelial elements such as are present in a true pancreatic cyst. The symptoms of a pseudocyst are due to pressure on the adjacent structures such as the stomach (causing nausea and vomiting), the portal vein or vena cava (leading to ascites) or the celiac plexus (causing pain in the upper abdomen and left shoulder).

The diagnosis of pancreatic rupture is exceedingly difficult even with operative intervention because the rupture may involve the posterior surface of the gland and no fat necrosis may be evident. An increase in the serum or urinary lipase and diastase

values may be of considerable value during the first few days even in slight injuries.

Treatment of the injury varies with different surgeons from simple suture of the capsule to tamponade and drainage exteriorly. Pseudocysts are easily broken, and therefore, are most easily treated by marsupialization, although drainage into an adjacent organ (preferably the duodenum) has been performed.

The author reports a case of pancreatic injury in a previously healthy 12 year old girl who sustained a violent blow to the epigastrium from a bicycle handlebar. Exploratory laparotomy undertaken 3 days later revealed only a yellowish brown peritoneal exudate. Two months later a pseudocyst developed, and following marsupialization an uneventful recovery ensued.

"Unexplained" Infarct or Intestinal Apoplexy
Comments on 2 Cases (Infarto "explicado" o apoplejia intestinal. Comentario sobre 2 observaciones) Alfredo Pierini. *Bolet Acad argentin cir* 1947 31 3 3

Two distinct types of mesenteric infarcts may be distinguished

1 The functional type possibly of an allergic origin which may subside spontaneously or under the influence of a treatment which combats the shock. This type may lead to vascular thrombosis and a resulting gangrene of the intestines. Adrenaline, on account of its vasopressor effect, has a beneficial effect on the condition.

2 The type caused by mesenteric endarteritis or thromboangitis. Ischemia is attributable to vasoconstriction and therefore an injection of adrenaline is contraindicated. Injection of novocain at the level of the superior mesenteric artery or spinal anesthesia, in addition to its therapeutic effect, may serve as a test valuable for the differential diagnosis between both types of infarct.

Anaphylactic shock provoked in animals may produce lesions similar to the functional or "unexplained" infarct in man. Allergens responsible for the condition in man may be of alimentary or bacterial origin. The resulting irritation of the sympathetic system in the splanchnic area leads to a functional infarct.

The author reports 2 cases in which a functional type of infarct produced an acute condition of the abdomen. In the first patient, a man 37 years of age, gastrectomy which was performed because of a gastric ulcer with resulting hypochlorhydria, and hepatic insufficiency caused by cholelithiasis, facilitated absorption of some ingested allergen. The operation disclosed a serosanguineous exudate in the peritoneal cavity, cyanosis and dilatation of the small intestines beginning approximately 1 meter below the duodenojejunal junction, and edema of the corresponding portion of the mesentery with dilated veins and also a dilated superior mesenteric artery. An intravenous injection of 1 mgm. of adrenaline was followed by peristalsis of the intestines (previously immobile) and reappearance of the normal color. The patient made an uneventful recovery.

The second patient, a man 50 years of age, also presented an acute condition of the abdomen. The operation disclosed subperitoneal edema, abundant serosanguineous fluid in the abdominal cavity, purple discoloration of 2 meters length of the small intestines, a hematoma in the corresponding portion of the mesentery and a dilated superior mesenteric artery. Intramuscular injections of 1 mgm. of adrenaline were followed by peristalsis and normal color of the intestines. The patient recovered from the operation.

JOSEPH K. NARAT, M.D.

The Effect of Radiation Therapy on the Nocturnal Gastric Secretion in Patients with Duodenal Ulcer. A correction. Erwin Levin, Anna Rasmann, and Walter Lincoln Palmer. *Gastroenterology* 1947 8 365

The third paragraph of this abstract which appeared on page 554 of the December 1947 issue reading "Treatment consisted of the daily application of 1,350 to 1,710 roentgens to the body and fundus of the stomach through two portals located anteriorly and posteriorly and was carried out for a period of 10 to 14 days" is not correct. The authors own words are as follows: All patients received a depth dose of 1,350 to 1,710 to the stomach in daily treatments through a period of 10 to 14 days. This was obtained by giving individual doses of 300 as measured on the skin with backscatter through two portals measuring 23 by 23 centimeters located over the body and fundus of the stomach, anteriorly and posteriorly."

GYNECOLOGY

UTERUS

Is Extensive Mutilating Surgery of Cancer of the Uterus Justified in the Light of Modern Knowledge? (Alla luce delle moderne conoscenze, nella terapia del cancro dell'utero, hanno ancora ragione di sussistere le tecniche chirurgiche ampiamente demolitrici?) Aldo Guasso. *Riv. ostet. ginec.*, 1947, 2, 107

Of 213 epitheliomas of the uterus 13 (15 per cent) were located in the corpus and 180 (85 per cent) in the cervix. Of the 33 cases of cancer of the corpus, 7 (30 per cent) were operable and of the 180 cases of cancer of the cervix 50 (13 per cent) were operable. Invasion of the lymphatics occurs only as an exception during the first 2 or 3 months of the existence of a malignant lesion.

Cancer of the cervix invades first the so-called interureterovaginal triangle. The author maintains that surgical intervention is useless and illogical if the cancer has invaded tissues beyond this triangle.

Radium introduced into the vagina and uterus is not capable of producing a cure as a rule but may be advantageously employed prior to the operation as roentgen therapy and so-called pleurotomy. The method also fails to produce a radical cure. Best results may be expected from applications of radium to the vagina and uterus followed by a hysterectomy and supplemented by deep x-ray therapy.

The terms radium surgery and roentgen surgery are applied to a concurrent use of surgery and irradiation. Theoretical considerations induced the author to prefer radium surgery to roentgen surgery although the method is not harmless.

The author came to the conclusion that cancer of the uterus is a curable disease and that the chances of cure are in direct proportion to the earliness of treatment.

JOSEPH K. NARAYAN, M.D.

A Discussion of the Preference for Total Abdominal Hysterectomy Instead of Subtotal Hysterectomy (Sulla discussione preferenza da darsi all'isterectomia totale addominale in confronto all'isterectomia subtotale) E. Debbiasi. *Fal. ginec.* Genova, 1947, 43, 233

A comparison is made between total abdominal hysterectomy and subtotal hysterectomy with regard to the morbidity mortality and complications of both. In the author's personal series of 185 hysterectomies for benign lesions he had a mortality rate of 1.1 per cent.

Factors in favor of total hysterectomy are as follows: (1) it is a radical procedure (2) the mortality rate is relatively low (3) the danger of cancer is eliminated (4) morbid changes in the stump are eliminated (5) there is relative infrequency of postoperative pelvic infiltrations, (6) there is a low frequency of postoperative disturbance of the intestinal function.

UTERUS

GYNECOLOGY

tion, such as meteorism and (7) it has a minor effect on the pulse.

Factors in favor of subtotal hysterectomy are that (1) it requires less time (2) the mortality is less than that of total abdominal hysterectomy (3) the normal shape of the vaginal wall is maintained, (4) the technique is easier especially when the pelvic floor is rigid (5) there is slightly less postoperative disturbance of the digestive tract and (6) there is less frequency of wound separation.

Both procedures are favorable with regard to temperature respiratory disturbances period of bed confinement, the possibility of preservation of the adjoining organs and the possibility of secondary intervention.

The author advocates complete hysterectomy as a standard procedure and believes that the subtotal procedure is indicated only in the presence of special considerations such as a desire to maintain the menstrual flow technical difficulties, and the necessity to shorten the procedure in view of a grave condition of the patient.

ANTONIO F. CRONZA, M.D.

ADNEXAL AND PERUTERINE CONDITIONS

A Classification of Ovarian Tumors Based upon Histogenesis. John A. Spencer and Philip J. Reel. *Am. J. Obst.* 1947, 54, 273.

The study of ovarian tumors has received a tremendous impetus of late years because of the careful study investigation, and reporting of a goodly number of the more unusual neoplasms and the attempt to work out a truly scientific classification on a histogenetic basis. The anatomicopathologic type of classification has been utilized by most pathologists to date. Histogenesis should shed additional light on these tumors when they are viewed from the broader clinical standpoint, particularly in regard to treatment and prognosis. From the radiologic viewpoint, a more universal classification based on the histogenetic background literature would clear up the very confused literature which exists.

It is still necessary to use descriptive terms to name different neoplasms properly but it is no longer practical merely to classify these growths into the cystic and solid and benign and malignant. In the absence of a universally accepted histogenetic classification, the authors present a modification of the one suggested by Schiller.

Ovarian neoplasms are divided into three broad classes

1. Ovario-genetic tumors derived from ovarian tissue
2. Nonovario-genetic tumors derived from ovarian foreign to the ovary but found elsewhere
3. Carcinomas of undeterminable histogenesis.

Following this basic structure and filling in the subdivisions led to the following classification

1. Ovario-genetic (tumors developing from tissues of true ovarian structure)

A. From the mesenchymal core of the ovary

- (1) From fetal cell remnants without error in sex chromosomes
 - (a) Granulosa cell tumor
 - (b) Theca cell tumor
- (2) From fetal cell remnants with error in sex chromosomes
 - (a) Arrhenoblastoma—male
 - (b) Disgerminoma—neuter
- (3) From interstitial tissues without sex potential
 - (a) Fibroma
 - (b) Angioma
 - (c) Myoma and fibromyoma

B. From the surface epithelium of the ovary (proliferation toward the müllerian duct)

- (1) Serous cystoma (tube)
- (2) Endometrioma (endometrium)
- (3) Pseudomucinous cystoma (cervix)

2. Nonovario-genetic (tumors developing from tissues not normally present in the ovary)

A. By displacement into the ovary in fetal life

- (1) Early—teratoma
 - (a) Mature—dermoid
 - (b) Immature—embryoma
- (2) Late—tissue from structures contiguous to the ovary during embryological development
 - (a) Hypernephroma—adrenal
 - (b) Mesonephroma—kidney
 - (c) Brenner tumor—urogenital epithelium
 - (d) Ganglioneuroma—sympathetic ganglia

B. By displacement into the ovary in adult life

- (1) Metastases of malignant tumors—Krukenberg

3. Carcinoma of undeterminable histogenesis

A. Carcinoma simplex, scirrhous carcinoma, pleomorphic carcinoma

A discussion of the histogenesis of each tumor is presented. The value of this concept lies in its aid toward the diagnosis, treatment, and prognosis of ovarian tumors. JOHN R. WOOD, M.D.

EXTERNAL GENITALIA

Microbial Pictures in Vaginal Smears. New Classification of Vaginal Biocenosis into 6 Basic Types. (Mikrobiel obrazovani. Nová třídění poševní biocenózy na šest základních obrazů.) O Jirovec, R. Peter and J. Málek. *Čas. p. sm.*, 1947 1: 1

More bacteriological classification of the cleanliness of the vagina into grades does not satisfy clinical needs, for it omits the gonococci, protozoa (*Trichomonas vaginalis*) and phytococci (mycoparasites, yeast micro-organisms).

With regard to the entire microfauna, microflora, and the histological elements, the authors classify the vaginal biocenosis from the broader microbiological

point into 6 basic groups, which they call anatomic vaginal smears and they number them with Roman figures (I VI).

The basic microbiologic vaginal smears and their types are:

I. The normal physiological smear from the vagina of a healthy adult woman. Types a, b and c: epithelial cells, few leukocytes (according to the phase of the menstrual cycle) Doederlein bacilli. Type d transition type. There is an increase in the number of leukocytes and bacilli.

II. Nonpurulent bacterial discharges (Type a). epithelial cells, few leukocytes and Doederlein bacilli, varied flora of bacilli and cocci. Type b Vibri type. Type c transition type semipurulent non leukocytes.

III. Purulent bacterial discharges. Type a. few epithelial cells, many leukocytes, varied flora of bacilli and cocci. Type b Streptococcal type. Type c Spirochaeta and fusiform bacteria type or both. Type d leptothrix type.

IV. Gonorrheal discharge. Type a acute Type b chronic.

V. Trichomonas discharge. Type a fresh infection, many leukocytes, scanty Doederlein bacilli more or less trichomonads. Type b culminating infection, abundant trichomonads and leukocytes, varied flora of bacilli and cocci. Type c chronic or latent infection (few trichomonads, few leukocytes, otherwise similar to type IIa).

VI. Vaginal mycosis. (Type a) nonpurulent mycosis few leukocytes, bacilli Doederlein, few epithelial cells and some kinds of pseudomycellium and candidium. Type b purulent mycosis many leukocytes, the rest like type a.

For the clinician it is quite sufficient to remember the basic groups (I VI) because the microbiologist informs him in slogans e. g. microbiologic smear II vibrio or microbiologic smear V fresh infection. The authors' experiences showed that nowadays we cannot do without a classification of the vaginal biocenosis from the broader microbiological viewpoint and that the treatment should be scientifically causal.

MISCELLANEOUS

Menstrual Toxin. Experimental Studies. O. Watkins Smith. *Am. J. Obst.* 947 541: 50

The atypical ergobulin derived from the endometrium during its late stages of retrogression is experimentally a powerful tissue damaging agent, capable also of inducing endocrine changes indicative of increased secretion and release of gonadotropic as well as of adrenotropic hormones. Immunologic studies suggest that this menstrual toxin and Menkin's canine necrocin are probably identical, which brings into close relationship the tissue damage in a species from different causes.

Fibrinolytic activity has been demonstrated to be closely associated with menstrual toxin and canine necrocin, and fibrinolyxin has been found in the circulating blood during menstruation, labor and the

toxemia of pregnancy also following surgery and in human pleural and peritoneal exudates

The pseudoglobulin fractions of all these fibrinolytic containing fluids, with the exception of the circulating blood following surgery have the property of prolonging the survival time and even occasionally of saving the lives of immature rats given minimal lethal doses of menstrual toxin. This property requires painstaking controlled experiments for its demonstration. Concentration of the pseudoglobulins is necessary. Protection appears to be a matter of quantitatively neutralizing the toxin and not of antibody formation in the ordinary immunologic sense

JAMES R. WOLFE, M.D.

Actinomycosis of the Internal Female Genitalia.
Report of 2 Cases. Everett M. Baker. *West J Surg* 1947 55 502

Actinomycosis may involve almost any organ of the body but comparatively few cases of this condition have been reported. A comprehensive review of the literature on this disease of the ovary and internal female genitalia has recently been made by the author

Actinomycosis of the ovary is a relatively rare disease. It is an infectious granulomatous disease characterized by the destruction of tissue suppuration, and an overgrowth of fibrous tissue. Most of the reported cases have been in the right ovary

The diagnosis is not easy even during laparotomy. The pockets of pus containing the ray fungus may not be clearly evident. The pathology resembles that of a neoplasm but being essentially inflammatory search for the elements of inflammation is imperative. Microscopic examination often fails to bring out the fungus immediately. The organism is slow in its invasion and slow in producing symptoms. A previous history of appendicitis or of a pelvic operation with an unusually slow and stormy recovery should make one suspicious of pelvic actinomycosis

Many types of treatment have been offered but the most important factor is early diagnosis.

Two cases of pelvic actinomycosis are reported in detail.

HARRY W. FICK, M.D.

Hemorrhages in the Menopause—the Clinical Significance of an Endometrium with Signs of Hormonal Influence (Ueber Blutungen in der Menopause. Speziell der klinischen Bedeutung eines Endometriums mit Zeichen hormonaler Beeinflussung). *Acta obst. gyna. scand* 1947 27 Supp. 6

The pathogenesis of postmenopausal vaginal hemorrhage particularly in patients in whom the endometrium shows signs of response to hormonal stimulation is discussed. Only patients who have been in the menopause for at least a year are considered. The necessity of excluding the presence of a malignant tumor in these cases is emphasized

The problems involved in the classification of different types of endometrial hyperplasia and their microscopic appearance having been discussed at

tention is called to the importance of differentiating the curettings from the endometrium which shows signs of response to hormonal stimulation from those taken in the presence of retrogressive hyperplasia or a uterine polyp. The latter have not been given sufficient prominence in the literature concerning endometrial hyperplasia in the menopause. The differentiation is difficult but may be materially facilitated by co-operation between the gynecologist and the pathologist and by constant examination of the uterine cavity with a uterine canal forceps. Attention is drawn to the microscopic details which in the experience of the Radimhemmet make the diagnosis of a uterine polyp from curettings possible

The literature concerning the etiology of an endometrial hyperplasia in the menopause is carefully studied particularly with regard to the coincidence between this condition and ovarian tumors of different types. A thorough description is given of the estrogen findings in the urine from patients with granulosa cell and theca cell tumors

One hundred and forty-eight cases of postmenopausal bleeding are presented in which the uterine mucosa showed signs of response to hormonal stimulation. The classification of the patients is made with reference to the following data noted at the first examination

- 1 Those with an ovarian tumor (30)
- 2 Those with a history of previous treatment with estrogenic hormones for a fairly long period or in considerably large doses (31)
- 3 Those without an ovarian tumor and without a history of previous treatment with estrogenic hormones (87). These are classified with reference to the history of their last menstrual period: less than 2 years previous to the postmenopausal bleeding (28) and more than 2 years (59). The reason for this grouping is that the cessations of the uterine and the ovarian cycles do not correlate with the menopause and that, consequently, bleedings of climacteric type may occur during the first years after the menopause

Thirty-six patients were in the menopause less than 2 years and received no treatment with estrogenic hormones. In 8 of these an ovarian tumor was present at the first examination. Only in 2 of the remaining 28 patients was an ovarian tumor noted later. The different microscopic appearance of the endometrium is briefly discussed

A close study is made of 81 patients who were in the menopause for more than 2 years and had received no treatment with estrogenic hormones. In 22 of these an ovarian tumor was present at the first examination. Of the 81 patients 70 were of great interest with regard to the pathogenesis of the endometrium which showed signs of response to hormonal stimulation in the menopause. The remaining 11 patients are not further discussed because

- 1 It was impossible to decide if disintegrated pieces of an endometrial hyperplasia or only of an endometrial polyp were present in the curettings (8)
- 2 No biopsy of the uterine mucosa was made (2)

3 It was impossible to decide the nature of the amenorrhea (1). The patient had been treated for several years with roentgen rays and the possibility of a temporary sterilization could not be excluded.

The microscopic appearance of the uterine mucosa in the 70 cases mentioned is discussed and a detailed account of the clinical course is given. In view of the clinical course and of the sex hormone findings in the urine it is most probable that ovarian tumors were present in at least 65 of the 70 patients (92.9%). In 53 of these 70 patients a laparotomy was performed. Microscopic verification of the ovarian tumors was available in 49 lesions: 43 granulosa cell or theca cell tumors (85.7%) 1 luteinoma (2%) 3 pseudomucinous papillary cystadenomas (6.1%) and 3 malignant papillary cystadenomas or adenocarcinomas of the ovary (6.1%). Three of the 49 ovarian tumors were histologically malignant and 5 were clinically malignant: 11.9 per cent of the granulosa cell tumors were clinically malignant.

The Radiumhemmet series of postmenopausal bleedings includes 90 cases in which clinical and histological examinations revealed nothing but a uterine polyp. Two of the patients were previously operated upon for carcinoma of the stomach and later developed metastases in both ovaries. A third patient has not been traced. Two of the remaining 87 patients later developed an ovarian tumor (2.3%). The considerable difference between the appearance of an ovarian tumor in patients with nothing but polyps (2.3%) and that of such a tumor in patients with endometrial hyperplasia (92.9%) obviously demonstrates the importance of a proper microscopic interpretation of the curettings.

In 8 of the 51 granulosa cell and theca cell tumors included among the 148 patients, there was a coincident adenocarcinoma of the fundus uteri (5.4%). 2 of these were histologically verified and 6 were considered as Group IX in the classification of Roser and Wall.

Three of the 8 patients were subjected to repeated curettage and it was noticed that the epithelial cells became increasingly atypical. The experience at the Radiumhemmet differs from that of Nakvak and Taylor who believe that the proliferative forces responsible for benign hyperplasia may predispose to the development of cancer.

In agreement with what has been stated before, it is advisable to submit to laparotomy all patients whose uterine mucosa shows evident signs of response to hormonal stimulation after being in the menopause for 2 years and who have received no treatment with estrogenic hormones. In cases in which it is impossible to perform a laparotomy radiological treatment is indicated. Granulosa cell tumors may be very radiosensitive.

The patients in whom it is impossible to differentiate between an endometrium with signs of response to hormonal stimulation and disintegrated pieces of an endometrial polyp should be kept under observation.

The connection between the type of the supplied estrogenic hormone and the microscopic appearance of the uterine mucosa is discussed.

Analysis is made of the estrogenic hormones in the urine from patients in the menopause. An increased amount signifies the presence of a granulosa or theca cell tumor.

PREGNANCY AND ITS COMPLICATIONS

OBSTETRICS

Clinical Statistical Study of Cases of Hyperemesis and Eclampsia Observed in the Clinic of Siena during the Period from 1929 to 1943 (Considerazioni clinico-statistiche sui casi di iperemesi e di eclampsia osservati nella Clinica di Siena nel quinquennio 1929-1943) *Arch. scien. clin.*, 1946 51 173

Three theories of the pathogenesis of hyperemesis and eclampsia may be distinguished (1) the placental, (2) the endocrine and (3) the theory based on alterations of the autonomic nervous system. Innumerable intermediate theories have also been advanced.

During the period from 1929 to 1943 35 cases of hyperemesis and 70 cases of eclampsia were observed in the Clinic of Siena. Hyperemesis was recorded in 0.3 per cent and eclampsia in 0.9 per cent of the entire obstetrical material. Of the 70 cases of eclampsia 8 occurred during pregnancy, 5 toward the end of pregnancy, 38 during the labor, and 19 in the puerperium. The predominance of cases during labor may be attributed to the untoward effect on the liver and kidneys of the effort of the organism to expel the fetus.

Recovery was recorded in 47 cases or 67.1 per cent. Twenty-seven patients who recovered had the eclampsia in labor, 11 in the puerperium, 5 during pregnancy, and 4 at termination of the pregnancy.

The percentage of the recoveries was higher in the women younger than 35 years than in older ones. Fatalities occurred in 17 cases, in 6 of older ones who had eclampsia in the puerperium, in 8 who had it during labor, and in 3 having it during pregnancy and in 1 patient who had it at the end of the pregnancy.

Operative procedures were employed in 46 patients: forceps accounting for 52.1 per cent of the operations, and version and extraction caesarean section, and induction of abortion accounting for the rest. Of 44 patients in whom forceps were applied 4 died. Of 12 patients who were subjected to version 5 died and of 6 who underwent caesarean section 1 expired.

Seventeen fetuses or 33.3 per cent, died. The author favors the placental theory of eclampsia which attributes the condition to autointoxication with poisonous substances originating from the fetus.

Hyperemesis is treated by the author symptomatically with sedatives, hormonal preparations, opiates and products causing hyperglycemia. In individualization is required because one drug may be efficient in one patient but not in another.

Eclampsia in the early stages is treated with venous section. Intravenous injection of magnesium sulfate, the administration of sodium sulfate by enema, and the use of decholin or other cholinergics or sedatives. In pronounced eclampsia in multiparas the

author recommends termination of the pregnancy through the vaginal route by podalic version, the application of forceps, or craniotomy. In primiparas the author advocates caesarean section.

ARTHUR F. CIPOLLA, M.D.
Acad. med.
 Tuberculosis and Pregnancy I. *Ruhm. Acad. med.* 1947 138: Supp. 197

In the beginning of the twentieth century pregnancy was generally considered to have a deleterious influence on tuberculous women. By and by, investigators altered the opinion as to this problem. Even nowadays however the majority of authors are of the opinion that pregnancy might influence tuberculosis, while the minority consider the tuberculous process to be independent of pregnancy. It has been pointed out that progression may occur post partum especially in cases with cavities. This is attributed to the descent of the diaphragm after delivery and the forced ventilation in connection with labor itself. Further it is stated that progression might be prevented by collapse treatment, e.g. pneumothorax or thoracoplasty.

The author has collected during pregnancy Dispersary of Stockholm. Parturition occurred in the year 1945 and the patients were controlled before pregnancy throughout gestation and after delivery.

The material comprises 121 patients, 115 of whom were not subjected to surgical treatment. There are 5 with pneumothorax and 1 patient with thoracoplasty. In the 115 cases first mentioned the tuberculous process was stationary in 83 per cent during pregnancy and the control period afterward. Progression was seen in 7 per cent and regression in 5 per cent. In 5 per cent both progression and regression were found.

As regards the cases with progression the tuberculous changes were benign. The fact that they frequently occurred immediately post partum indicates that the physical effort of the labor itself might play a certain role. Otherwise there would not be found among these patients that suggested that the pregnancy had any influence upon the tuberculous process. In the cases with regression improvement may begin before or after the patient has become pregnant as well as before or after delivery. The number of cases with more regression (57%) corresponds fairly well to that of those with more progression (72%). Thus it is evident that the alterations which occur now and then during pregnancy might well be ascribed to the usual clinical changes in tuberculosis.

In the 5 per cent in which progression alternated with regression during pregnancy there was no correspondence in the course of the changes. In these cases there was no marked deterioration post partum.

Lymphopathia Venereum Complicating Labor
 Irwin H. Kaiser and Edwin L. King. *Am J Obst.* 1947 54 219.

Lymphopathia venereum complicates pregnancy primarily by the inflammatory lesions it produces in the mother which impede the progress of labor. The dystocia produced by this disease falls into 2 anatomic groups. The first is caused by the elephantiasis esthiomene variety of vulvar lesions. Its management to now differs from that of similar soft tissue outlet dystocia due to other causes. The second type is caused by the extensive scarring of the soft tissues in the pelvis, of which the rectum is usually the first involved. This is due primarily to the virus and also to the usually associated secondary infection. The problems presented by this second type are unique in obstetrics.

This report is based on an analysis of 38 labors in 28 women with pelvic lymphopathia venereum observed at the Charity Hospital in New Orleans, Louisiana, between 1937 and 1946 plus a survey of 124 instances of this condition which appeared in the literature.

No individual is known to have had an exacerbation of the lymphopathia in association with pregnancy.

The 162 labors now recorded in the literature have a maternal mortality rate of 6 per cent but this figure appears to exaggerate the actual risk. Force in delivery has played a large role in the reported fatalities. Version and extraction is absolutely contraindicated. Death is usually due to rupture of the rectum or uterus, which may occur with spontaneous delivery.

If soft tissue scarring due to lymphopathia venereum is widespread in the pelvis, the patient should be delivered by cesarean section. A trial of labor may be permitted but if the presenting part fails to descend to the outlet, cesarean section rather than any form of pelvic delivery should be performed regardless of the dilatation of the cervix. If the patient delivers per vaginam she should be watched diligently for signs and symptoms of rupture of the uterus or rectum. The appearance of peritoneal irritation or shock should suggest exploratory laparotomy.

Colostomy in itself presents no special obstetric problem other than that found in other patients with pelvic lymphopathia venereum. In the 38 labors in the presence of lymphopathia venereum and rectal stricture observed in the Charity Hospital in New Orleans, there were no maternal deaths. Three cesarean sections were performed.

JOHN R. WOLFF, M.D.

Painless Labor with Continuous Caudal Analgesia
 (O parto indolor pela analgesia caudal continua)
 Francisco Cerruti and Menotti Laudisio. *Rev Paulista med.* 1946 29 1.

Using a steel needle, in preference to a catheter and 1 per cent novocain in physiologic salt solution at the rate of 30 drops per minute for the first 30

minutes and 15 drops per minute subsequently the authors tried the method of continuous caudal analgesia in 20 cases of labor and succeeded in introducing the anesthetic in 17. They found it impossible to pass the needle through the sacrococcygeal hiatus in 2 cases, and the needle perforated a vein of the epidural space in 1 case causing inundation of the sacral canal. Analgesia was complete in 13 cases and partial in 4. There were no accidents or complications and no fetal deaths. The largest quantity of anesthetic used was 350 c.c. and the smallest 50 c.c. The maximal duration of anesthesia was 6 hours and 25 minutes, the minimum 30 minutes. The authors draw the following conclusions.

Under continuous caudal analgesia a painless labor can be obtained in from 75 to 80 per cent of the cases. The anesthetic should be started when labor is in full swing with a cervical dilatation of not less than 3 to 4 cm. and the method should be used only in cases in which transpelvic delivery is possible.

Continuous caudal analgesia usually causes a decrease in the frequency of the uterine contractions with slight shortening of their length and according to the level of the cutaneous anesthesia may produce secondary inertia. Nevertheless delivery is not prolonged because anesthesia facilitates cervical dilatation and allows the fetal head to reach the pelvic floor more quickly.

The fetal head frequently stops at the perineum because the abdominal wall is anesthetized and the patient is unable to exert voluntary action. Kristeller's maneuver of expression eliminates this deficiency and becomes almost indispensable to delivery of the cephalic pole. However an abdominal belt was used in 2 cases and found to replace Kristeller's maneuver to advantage because it exerted more uniform pressure. When these artifices do not result in spontaneous delivery a low forceps may be applied. In occiput right posterior presentation the fetal head frequently reaches the perineum without the occurrence of internal rotation.

One of the greatest difficulties encountered in continuous caudal analgesia is the introduction of the needle into the sacral canal because edema of the region often covers up the sacrococcygeal triangle which is an indispensable reference point for the correct placing of the needle.

Uninterrupted observation of the patient is essential during the use of the method. In their cases the authors encountered a sudden rise of the cutaneous level of anesthesia, complete and rapid anesthesia with small quantities of anesthetic, a fall in the blood pressure and other occurrences which required the immediate intervention of the anesthetist.

The drip method is superior to the fractionated dose method because it is easy to change the number of drops used when this becomes necessary while 30 or 30 c.c. of anesthetic solution injected at one time cannot be withdrawn from the sacral canal. The method also allows the use of 2 tests: one to detect perforation of the dura mater the other to identify a wrongly placed needle.

variations in the rate of transfer of substances during different periods of pregnancy.

In women also the results of investigation following the intravenous injection of radioactive sodium showed that the rate of transfer of sodium per unit of weight of the placenta rose noticeably with the progress of pregnancy. The authors correlate certain morphological findings observed by them with this conclusion. They found that in the early stages of pregnancy the villi were relatively few but, at the same time large and thick walled and covered both by Langhans and by syncytial layers. In later stages the villi increased in number and at the same time became smaller and more thinly walled and without a Langhans layer.

By means of serial section examination of the placental tissue the authors endeavored to demonstrate the changes of villi or their vessels which might explain a raised permeability in the placental wall under certain conditions. Placentas were selected which showed marked structural changes grossly such as are often found in toxemic patients.

One such placenta from a woman with toxemia is described. The patient had been given a transfusion of blood containing ellipocytes before delivery and a number of the cells were seen to have gone over to the fetus. Several variously sized dark, blood filled foci stood out plainly in a microsection of the fixed placenta. The villi were considerably wider apart than in the normal placental tissue and their vessels were engorged with blood. Serial sections of a villus wall showed it growing thinner and thinner with the capillaries finally seen lying naked in the intervillous spaces at places the walls were indistinguishable between lightly packed fetal red cells which seemed to pass directly into the intervillous spaces of the mother. In places only a thin endothelial layer separated the fetal and maternal blood. Some sections demonstrated villi with walls without the syncytial layer. Gaps in the villus walls were seen filled with compact blood cells both fetal and maternal.

Infection experiments on placentas with sterile solutions of rice starch of a certain size of grain were

carried out. The umbilical vein of a fetus delivered by caesarean section (in the case of an induced abortion for medical reasons) was injected with the starch solution, the fetus being allowed to live while the blood was pumped around the body and into the placenta. Histological examination of the placenta revealed rice grains in the villous spaces. Villus wall none were seen in the villous spaces. Villus wall changes favoring the passage of substances from fetus to mother were noted.

PERRY B. CHASE, M.D.

The Results of Three 5 Year Studies of Hydatid Mole and Chorioepithelioma on the Pacific Coast. Albert W. Holman and Elizabeth H. Schirmer. *West J. Surg.*, 1947 55 545

This article is based on a combined 15 year study and includes the findings reported on 426 moles and 107 cases of chorioepitheliomas. 69 of the latter followed hydatid mole.

Hydatid mole in this series was not as common in patients over 40 years of age as it was thought to be by other observers. Hydatid mole is a disease of the ovum in early pregnancy. The teaching that excessive enlargement of the uterus occurs in the majority of cases of hydatid mole is false and should be discontinued. Curettage is preferable to hysterectomy in the treatment of hydatid mole. Hysterectomy and/or oophorectomy has no place in the treatment of hydatid mole. Chorioepithelioma, occurring several years following hydatid mole or pregnancy is the result of an intervening abortion which has not been recognized.

Biologic pregnancy tests have not yet attained their proper place in the diagnosis and prognosis of hydatid mole and chorioepithelioma. Both positive and negative pregnancy tests should be repeated and verified in cases of hydatid mole and chorioepithelioma. Sufficient attention is not paid to the presence of lutein cysts of the ovary accompanying hydatid mole and chorioepithelioma. Oophorectomy is not necessary in the treatment of chorioepithelioma. Pulmonary metastases are the greatest single cause of death in chorioepithelioma.

CHARLES BARON, M.D.

by obstruction of the ureter with coagulum (6) median displacement of the upper part of the ureter (7) spilling of the contrast medium outside the pelvis and renal parenchyma because of their rupture, (8) a negative image through lack of elimination of the medium, which would suggest a grave lesion of the parenchyma and (9) pleural effusion and decrease in the movements of the diaphragm on serial examination during the subsequent days.

Retrograde pyelography may be contraindicated by the seriousness of the clinical picture. In addition it may increase the hemorrhage and carry infection to the kidney. Cystoscopy, pyelography and the indigo carmine test to study the function of the opposite kidney should be used only in mild and average cases which are kept under observation in a specialized milieu. In an emergency service attended by general surgeons, intravenous urography constitutes a minimal requirement and should be omitted only in exceptional cases.

The expectant method should be reserved for minimal local and general pictures which represent closed lesions of the type of simple contusions or small parenchymatous fissures without rupture of the capsule, calices, or pelvis. Descending urography showing the absence of extravasation of contrast medium will militate in favor of expectation as will also congenital absence of the opposite kidney even in the presence of persistent hemorrhage.

When the acute clinical picture demands it (frank anemia, hypotension, hematuria, palpable hematoma) after treatment of shock and if possible intravenous urography exploratory lumbarotomy is performed or laparotomy when associated lesions are suspected. Without going to the extreme of conservation at all cost, the kidney must be respected if there is any possibility of functional recovery even cortical lesions reaching the calices may be closed with careful sutures preferably of ribbon gut (Loweley and Menning) or including a piece of muscle or fat in the line of suture to give it greater strength. In other cases it will be necessary to take recourse to partial resection, heminephrectomy or even nephrectomy in the presence of a pathologic kidney.

When the conservative procedure is pushed too far and is used in extensive parenchymatous wounds, abundant scarring may later be responsible for serious complications which may reach obstructive hydronephrosis, calculus formation, pyonephrosis, perinephritis and final atrophy of the kidney. But when the conservative method follows the classical indications and is used in fissures of the parenchyma even with reparable wounds of the pelvis, it is rewarded by immediate successful results and by absence of late complications.

Nephrectomy the operation of choice gives the best immediate and late results. It is indicated in great destructions of the parenchyma, detachments of the pedicle and irreparable lesions of the pelvis and/or ureter. In open lesions from cutting instruments or firearms with abdominal or lumbar injury surgical intervention is indispensable as soon

as shock has been overcome. The operation may or may not be started with a laparotomy to attend to the associated intestinal, hepatic, or other lesions and the kidney may be approached through the same incision or through lumbarotomy. In wounds from cutting instruments it will often be possible to suture the parenchyma. Wounds from fragments of grenades or bombs and the presence of pieces of clothes and of soil in the tissues will indicate immediate debridement, resection of the tract, removal of the foreign bodies and treatment of the renal lesion.

RICHARD KEMML, M.D.

Contribution to the Diagnosis and Treatment of Papilloma of the Renal Pelvis (Ein Beitrag zur Erkennung und Behandlung des Nierenbeckenpapilloma) Kurt Tschirntsch, *Deut. med. Wochschr.* 1947 72: 442

Papilloma of the renal pelvis is extremely rare. According to European and American statistics its incidence is about 0.65 per cent among all kidney tumors. Only 200 cases have been published in the entire literature. Histologically and biologically it is closely related to warts. Patients with papillomas of the urinary tract often also reveal papillomas of the skin.

The main clinical symptoms are hematuria and pain which in most cases occur in attacks starting and stopping abruptly. It is difficult to make the correct diagnosis prior to surgery and to differentiate the papilloma clinically from other forms of pathology in the kidney pelvis (parenchymatous tumors, calculi). However the diagnosis can be established if tumor tissue is found in urine obtained by catheterization of the ureter. Also, when villi from the papilloma are found in the voided urine and cystoscopy reveals the absence of papillomas in the bladder the diagnosis is certain. It has been shown that villi from the diseased portion can get into the healthy kidney by reflux and thus may cause diagnostic errors as to the site of the tumor. The most valuable help in the diagnosis is retrograde pyelography, especially in early cases. Later on when hydronephrosis or pyonephrosis has developed the filling defects fail to show up in the pyelogram. However the pyelogram is not infallible. Very small papillomas may be overlooked, or soft calculi or coagulated blood may be mistaken for tumors.

The only effective treatment is surgery. The author is opposed to pyelotomy or nephrotomy because of the danger that very small papillomas may be overlooked. Moreover the risk of dissemination and carcinomatous degeneration of the papillomas due to the operation is so great that conservative surgery is not justified. The only safe treatment is nephrectomy plus ureterectomy. The ureter should be removed in its total length including the intramural portion in the wall of the bladder. Recurrences and metastases in the ureter probably by way of implantation have frequently been observed.

The prognosis is not altogether good even in cases in which surgery was done at an early stage. The

question of malignancy in this seemingly benign tumor has been a subject of discussion for a long time. In 1914 Scholl of the Mayo Clinic reported 8 cases which were malignant clinically and histologically. Primary malignancy or secondary carcinomatous degeneration is estimated to occur in about 70 per cent of the cases. Recurrences and metastases occur usually within the first 3 years after surgery; late metastases seem to be rare.

The author reports a case of his own observation which was correctly diagnosed by retrograde pyelography.

WILLIAM M. SCHWARTZ, M.D.

A Clinical and Pathologic Anatomical Study of Tumors of the Kidney in Children Based on a Series of 18 Cases. Lino F. Vucok. *Acta chirurgica* 1947 95 333

The author reports 18 cases of tumors of the kidney in children from 2 months to 8 years of age. These cases are all from hospitals in Finland and none has previously been reported.

The first symptoms were listlessness, anorexia, weight loss, anemia, slight fever and rarely hematuria. In 17 children the tumor was discovered on admission. The period of time which had elapsed between the first appearance of symptoms and the diagnosis was from 1 day to 10 months, the average being 4 months. Wrong diagnosis, or failure to discover the tumor occurred once in 4 patients, twice likewise in 4 patients, three times in 1 patient and four times also in 1 patient. The time lost in this way was from 27 days to 10 months. The author stresses the rare and late metastases from these tumors and the late breakthrough of the renal capsule and encourages earlier diagnosis through an awareness of this disease on the part of those who treat the disease of children.

In the author's series nephrectomy was done transperitoneally in 5 patients and retroperitoneally in 13. He favors the former method as it allows for ligation of the renal vein before mobilizing the tumor.

Nine patients were given postoperative x-ray therapy but all died of recurrences. Of the total series 14 patients died of recurrence within the first 16 months after operation, 4 patients are still living after 18 months but 1 patient has already been found to have recurrence.

The tumors included both the nodular and solid, as well as the sarcomatous and papillary variety. Histologically they were 17 of 18 different types ranging from the most primitive sarcomatous forms to adenomatous varieties containing glomerular elements. The so-called capsule is regarded as a sclerotic layer of renal tissue.

JOSEPH F. MURPHY, M.D.

Primary Carcinoma of the Ureter. J. M. Hundley and J. A. Hunter. *J. Urol.* 1947 58 122

The authors present a case of carcinoma of the ureter to which the danger of retrograde extension to the renal pelvis from the "ureter" is emphasized. The authors state that although a low grade tumor either clinically or

pathologically and must be considered a malignant tumor.

The lesion is most common in the sixth and seventh decades and occurs in the male more often than in the female. The usual symptoms are hematuria, pain and a tumor mass. Pathologically primary carcinoma of the ureter is either papillary or papillary and spreads early and more extensively than a similar lesion of the bladder. Ureterectomy with segmental cystectomy and a retroperitoneal one-stage operation is the procedure of choice.

The case presented was that of a 56-year-old female who was admitted to the University Hospital of Baltimore, Maryland, complaining of hematuria for a week. A retrograde pyelogram showed a filling defect in the left ureter of kidney although the filling defect was from the left ureteral orifice. Nephrectomy and ureterectomy was done but the lower portion of the left ureter was not removed as it seemed to be uninvolved. The microscopic picture was that of benign papilloma of the ureter. Three months later cystoscopy revealed a growth projecting from the left orifice. The lower segment of the ureter was then removed and a large tumor was found. A recurrence at the lumbar incision was found also. The patient died 6 months after the pyelorectomy because of the recurrence and metastases.

JOSEPH E. MURPHY, M.D.

BLADDER, URETHRA, AND PENS

Visco-Rayopaque in Cystourethrography. C. F. Richards. *J. Urol.* 1947 58 113

Cystourethrography is a valuable diagnostic procedure which has not been generally used because of technical difficulty and because there has been no truly satisfactory medium. The author presents his experiences with a new water-soluble viscous radioopaque substance visco-rayopaque which he believes is safer and more efficient than any contrast media previously proposed for urethrography.

The cystourethrogram is helpful in the diagnosis of any condition which produces gross anatomical alteration in the contour of the bladder or ureter. It is an adjunct to the usual procedure of urethroscopy and in cases in which the patient is unable to undergo the procedure it may be the only approach to an accurate diagnosis of the present condition. Its outstanding advantage over cystourethrography is that it provides a permanent graphic record which may be compared with later studies to determine its value in evaluating the progress of the disease under consideration.

Viscourethrography is a roentgenogram of the bladder and urethra where cultures have been found to be present in the prostatic urethra. The authors state that contrast medium is not present in the ureter when an opaque cystogram is obtained. The authors believe that a satisfactory method of urethrography can be achieved by the use of visco-rayopaque.

the attributes of the ideal cystographic medium but it must in addition be somewhat more radio-opaque and also considerably more viscous. The necessity for increased radio-opacity is due to the fact that x-rays in passing through the urethra, are interrupted by such a relatively shallow column of the contrast medium that to produce a satisfactory roentgenogram, this thin layer of medium must be almost totally opaque to the rays at the required exposure. Also, the changes in structural pathology encountered in this region are frequently so delicate that the urethrogram must have an exceedingly sharp and detailed outline demonstrating the most minute anatomical abnormality.

The necessity for increased viscosity is due to the fact that, when at rest, certain segments of the normal urethra are occluded by the sphincters and the pressure of the surrounding tissue. To completely visualize these segments on a roentgenogram it is necessary to expose the x-ray film while they are temporarily opened by the flow of an opaque medium through their lumina. This may be accomplished either by voiding the medium from the bladder or by injecting it retrograde through the urethral meatus at the time of exposure. However for the column of opaque material which is passing relatively slowly through these segments of the urethra to open them sufficiently to produce a satisfactory outline the opaque material must have a viscosity many times that of ordinary aqueous solutions.

Up to recently, the substances which were most frequently used for urethrography contained some type of an iodized oil. They had a tendency to be somewhat irritating to the mucosa of the urethra, due to free iodine being liberated from the compound when exposed to air, light, or high temperature. Furthermore, having an oil base, there were certain inherent disadvantages to any nonwater soluble agent inasmuch as they are not miscible with the urine and sometimes produce an irregular outline due to globules of the dye mixed with the urine or aqueous cystographic medium. The most serious objection to the iodized oils is the possibility of introducing some of the medium into the general circulation, producing a fat embolus.

Visco-rayopake is an experimental organic iodide developed recently as a radiocontrast medium. It seems to be a substance which meets every requirement for the perfect urethrographic contrast medium. It is more viscous than any of the previously proposed media. It produces sharper outlines and better detail than any other, except perhaps the iodized oil. It seems to possess all the advantages of the iodized oil and at the same time has none of their potential dangers and disadvantages. It is water-soluble and therefore miscible with urine and aqueous cystographic media. Most important of all its use carries no risk of fat embolus or general systemic defect even if it should inadvertently be introduced into the circulation during urethral injection. The authors have used visco-rayopake in 54 patients with excellent results. They have experienced no evidence of local

or generalized irritation or toxicity, nor has there been anything suggestive of an allergic phenomenon. There have been no reports in the literature of any type of serious reaction to this substance.

The author outlines the usual procedure for making cystourethrograms as follows:

1. Adequate preparation of the patient with purgatives and enemas.
2. The patient empties his bladder as completely as possible.
3. A plain x-ray of the abdomen is made.
4. A small soft rubber urethral catheter is introduced into the bladder and the residual urine, if any, is measured.
5. A 2 to 4 per cent solution of sodium iodide is introduced into the bladder, the amount and the concentration varying with the circumstances.
6. The catheter is withdrawn, leaving the iodide solution in the bladder.
7. With the patient in the supine position, 25 c.c. of visco-rayopake is injected slowly into the urethra, the last 5 c.c. during the exposure of the film. Having the patient relax completely and attempt to void facilitates this injection by opening the external urethral sphincter. The x-ray tube is centered directly over the symphysis pubis.
8. With the urethral meatus occluded the patient turns on his side so that the pelvis is at a 45 degree angle to the vertical plane, the lower thigh and leg in complete flexion and the upper thigh and leg in complete extension. A film is exposed in this oblique position during the injection of an additional 5 c.c. of contrast medium.

9. The patient voids. If there is more than 50 c.c. residual left in the bladder, a catheter is passed at the end of the procedure to remove the remaining sodium iodide solution.

In a large majority of patients, these two views will give all the desired information. If a very sharp outline of the bladder is desired, a more concentrated solution is used. If a bladder filling defect is suspected, such as an enlarged prostate neoplasm, or nonopaque calculus, then a less concentrated solution is indicated. If one is interested primarily in delineating the bladder outline, a maximum amount of solution should be instilled. If one is looking for encroachment on the bladder's lumen, a smaller amount of solution would be instilled.

The author concludes that visco-rayopake is believed to be the safest and most efficient urographic contrast medium yet produced.

ROBERT O. BEADLES, M.D.

Carcinoma of the Bladder James T. Priestley, J.
Am. J. Surg., 1947, 134, 507

Many factors must be considered in deciding on the most desirable type of treatment for a patient who has carcinoma of the bladder. These include the size, grade, and location of the lesion, the degree of infiltration, whether the lesion is single or multiple, whether the ureterovesical orifice is involved on one or both sides, the status of renal function, the

with a certain amount of giant cells. These nodules resembled tubercles however no trace of caseation was found. Furthermore the giant cells were not of the Langhans type with horseshoe arrangement of the nuclei rather they resembled foreign body giant cells, their nuclei being arranged more to the center of the cell. Closer investigation revealed that the cytoplasm of the giant cells as well as the epithelioid cells contained numerous small droplets of a fatty substance which obviously was paraffin. Similar findings were revealed in a later biopsy from the edge of the ulceration.

In a series of 6 interventions, the paraffinoma was excised and a penis of normal length and shape formed by transplantation of skin from the pubic region. The result was satisfactory from the anatomical as well as the functional point of view.

It should be mentioned that the patient consistently denied ever having had an infection of paraffin however in view of the histological findings, there could be no doubt about the diagnosis.

WERNER M. SOLMITZ, M.D.

GENITAL ORGANS

Some Observations on Transurethral Prostatic Resection. Reed M. Nesbit. *A. England J. M.* 1947 837 207

The author emphasizes certain details of technique that have been found necessary to the successful execution of transurethral resection. This operation has been performed in the University of Michigan Hospital at Ann Arbor since October 1931 and experience has shown that prostatic resection possesses many attendant hazards and that there are numerous pitfalls in the performance of this technically difficult operation. Most of these can be considered under trauma and hemorrhage.

One of the most frequent causes of immediate and late complications is urethral trauma. When the urethra is traumatized by forceful introduction of rigid instruments that are too large there results an introduction of infection manifested by the development of local tenderness of the urethra and general sepsis. Later the development of stricture completes the cycle and may leave the patient with a lesion which is just as debilitating and infinitely more difficult to treat than prostatism. Urethral trauma is usually avoided if the surgeon does not introduce the standard size resectoscope into the urethra which fails to accommodate easily a No. 30 Fr. steel sound. When smaller urethras are encountered one may use a resectoscope having a sheath of smaller than standard diameter. If this is impractical, the surgeon has two procedures that can be followed: (1) meatotomy will often permit the passage of the resectoscope; however in some cases the remainder of the urethra is too small and then perineal urethrotomy is indicated. At the University of Michigan Hospital, approximately 35 per cent of the patients operated on by resection require meatotomy whereas perineal urethrotomy is performed in 20 per cent.

Other indications for perineal urethrotomy include (1) severe urethritis (2) shortness of the penile suspensory ligament (3) excessive length of the prostatic urethra (4) abnormal position of the prostatic gland. In performing resection on large glands that is those in which 50 gm. or more of tissue is removed, urethrotomy is used in 30 per cent of the cases, in comparison to 20 per cent of all cases. In the resection of large glands the procedure allows an increased maneuverability that has facilitated the technique of operation.

It can be accepted as an axiom of transurethral surgery that the resectoscope must be freely and easily contained by the urethra at all times. Single exception to this rule is when the instrument is held tightly in the prostatic urethra by cancer or by contraction of the vesical neck. Whenever perineal urethrotomy is indicated to effect this purpose it should be done, for it is simple to perform and the patients suffer little or no inconvenience from it. They rarely pass urine through the incision and none develops stricture at the site of operation.

Another form of trauma occurs when the resectionist cuts too deeply into vulnerable areas. The most frequent are perforation of the prostatic capsule and injury of the external urinary sphincter. Minor perforations rarely give rise to morbidity and are probably of little clinical significance. Healing of the defect probably takes place quite rapidly and is enhanced by the catheter diversion of the urine. Extensive perforation however may give rise to pelvic cellulitis and extravasation and if not recognized and promptly treated by adequate drainage will terminate fatally.

Urinary incontinence following resection occurs when the external sphincter is cut with the resectoscope and is a complication which can be avoided even by the inexperienced resectionist if due care is exercised in the performance of a sound technique. Except in the presence of infiltrating cancer or inflammatory contracture that involves the membranous urethra, the proximal margin of the external sphincter can be recognized by certain anatomic properties of the structures that go to make up the area. The membranous urethra is an immobile structure whereas the adjoining prostatic urethra is slightly mobile, but the mucosa of each structure is tightly adherent. When the prostate gland is moved the surface configuration at the prostatomembranous juncture is altered by wrinkling in a manner comparable to the wrinkling of the bellows that connects two Pullman cars. The mucosal folds that are created in this manner are transversely disposed and extend around the entire circumference of the urethra. They can be recognized easily when observed through the resectoscope and are brought into view most effectively if the instrument is moved in and out through a short excursion while the area is being inspected. Fortunately this wrinkling phenomenon tends to increase as the transurethral resection progresses because of the increased mobility of the gland that is effected by the operation so that the surgeon can al-

Fig. 1. Diagram showing of tract in a bladder outlet produced by hypertrophy of the lateral lobes and median lobe of prostate.

ways demonstrate that the prostatic membranous junction toward the end of the operation and can safely excise it all down to that point without fear of sphincter damage.

Hemorrhage in every prostate resection is accompanied by blood loss, and it is important that the surgeon have more or less accurate information regarding the amount of blood loss. A method of estimation of blood loss is described by the author in 1931 and provides the surgeon with objective data regarding the patient's need for replacement therapy.

The successful control of bleeding during the operation depends on certain details of technique which are acquired with experience. Bleeders are easily recognized and quickly arrested when the walls of the prostate are exposed. The incision for the resection is made rapidly to traverse the entire operative field in a variety of ways at the membranous urethra but then the operation is irregular and the anastomosis is irregular. The irregular surface tends to increase the difficulties by enhancing the formation of clots which in turn conceal anastomosis in blood. The experienced resectionist takes care to keep each exposure of the cut surface extended full length of the adenomatous mass that is being resected. When long masses of tissue are to be excised the operator while cutting may find the path of the instrument toward himself with the lower extremities that larger slices of tissue than would otherwise be permitted by the full exposure of the field can be excised. When the distal end of the adenomatous mass comes into view the resection of the mass is stopped and the cut surface is exposed forward and small fragments of tissue are cut off. The fragment of tissue is then held in the stream of water and with a sharp instrument a small piece of tissue is removed from the

excavation and the operator can examine the tissue within the excavation or continue to remove his cutting maneuvers. By a technique of this kind the cut surface can be kept smooth and the bleeding point and blood clot is removed.

The injection of various substances into the prostate gland to prevent bleeding during operation is not recommended.

Postoperative control of bleeding presents a problem, and it was formerly the practice of the author to irrigate the bladder with water every 1 or 15 minutes during the first 24 hours after operation. In the past 2 years this was replaced by the instillation of thrombin into the prostate gland. The discontinuance of postoperative irrigation in a running comparative series, it was found that the elimination of irrigation was the factor of greatest importance in controlling the postoperative bleeding. Consequently at this time the author does not irrigate after resection. With this there have been fewer cases of catheterization ever before.

Operative Technique The author presents a résumé of the technique that has been employed in prostate resection. In this procedure there are three phases of operation. In the first phase of the operation the apex of the prostate is removed. The apex of the prostate is the apex of the internal vesical sphincter. The second phase consists of removal of the remaining structures from within the prostate gland. The third phase consists of removal of the remaining structures touching the internal urethra.

In the first phase the resectoscope is used to enable inspection of the anterior wall of the prostate urethra. The anterior commissure is seen and one of the masses of the lateral lobes is found to bulge prominently more than the other. The field of vision. This one is chosen for the beginning of the operation. The external cut is brought into contact with the external urethral orifice. The incision is made in the urethra and along with the resectoscope and a fragment of tissue extending the full length of the lateral lobes is excised in all of its extent.

The observation of the morphology of the prostate is of primary importance for it is in this manner that the surgeon gauges the extent of what should be excised. The prostate is a mass of tissue which have a characteristic appearance. It varies only when there is a cystic lesion or a stricture. The appearance of the prostate is different from that of other tissues. The adenomatous prostate gland. It has a soft appearance when viewed through the resectoscope. The internal urethral orifice is surrounded by its circular muscle fibers. The prostate has a firm appearance and is not easily cut.

When a resection is only performed in the first phase of the operation a third phase of the

Fig. 2. Diagram showing cone-shaped area left after first phase of operation has been completed. Although a large part of the median and lateral lobes has been removed, there still remains much prostatic tissue to be removed from concave prostatic fossa.

can safely be excised in the same line, but if muscle fibers are recognized at the inner end of the furrow the operator must cut no deeper at that point. Instead the resectoscope is rotated a few degrees laterally so as to begin its next excision of tissue fragment. This slice of tissue and each successive one extend like the first fragment, the full length of the gland and the furrow that is formed by the second cutting stroke is confluent with the first, and like the first furrow is deepened until circular fibers of the internal sphincter are encountered then the resectoscope is again rotated a few degrees and another adjoining furrow is made. It is noteworthy that each of the successive cuts exposes a small arc of internal sphincter but that the individual furrows extending toward the apex of the prostate converge at a point, for the membranous urethra is a fixed point. The confluent furrows that successively expose the circumference of the internal sphincter create a cleft extending from that circle out to the apex, and the cleft that is created in the manner described often encircles the whole mass of prostate. These masses are composed of portions of the lateral lobes and of the median lobe, and when encircled as described and cut off from the peripheral circulation the entire mass can be cut up into fragments quickly and bloodlessly. In the resection of small obstructing glands or contrac-

Fig. 3. Diagram showing how prostatic tissue is removed from concave fossa down to capsule of prostate. At conclusion of this second phase of operation there remains only some prostatic tissue at apex of gland adjacent to and just above external voluntary sphincter muscle. In the third stage of operation this remaining tissue at apex of prostate gland is removed.

tures, the cutting maneuvers in the first zone of operation often entail only the removal of a shallow depth of tissue so that there may be no encirclement of a tissue mass. When the first phase of operation has been concluded there is a cone-shaped space extending from the apex of the gland to the circle described by the internal vesical sphincter. The walls of this cone are smooth and are composed of prostatic tissue, and any bleeding points are easy to identify.

The second phase of operation is concerned with the removal of adenomatous tissue from the concave prostatic fossa. In this zone the cutting loop enters the prostatic mass distal to the circular fibers of the internal sphincter and each excursion of the loop extends almost to the external sphincter where a small mass of tissue is allowed to remain as a bulwark against injury of the sphincter. In this zone the first cut is made anteriorly and successive cuts are made in the same furrow until the capsular structures are recognized. Successive cuts are made lateral to the original furrow until capsular structures come into view and dissection is continued with the object of creating a cleft that is peripheral to the adenomatous mass of tissue. Digital palpation of the gland during the resection within the posterior half of the fossa is essential to accurate and safe dissection. With a finger in the rectum the surgeon is able to palpate quite accurately the thickness of the adenoma and when nodular masses are relatively inaccessible because of unusual position, to push them upward into the path of the cutting loop. By peripheral dissection in the second zone of operation the adenomatous mass is devascularized so that the free mass that is finally isolated on the floor of the urethra can be expeditiously and safely excised by rapid resection.

At the conclusion of the second phase of operation the surgeon is able to view the entire fossa from the vantage point at the apex of the gland. In the distance he can see the denuded internal sphincter and in the foreground he is able to inspect the smooth concave wall of the prostatic fossa. Bleeding points are readily discovered.

The final phase of operation requires a meticulous and careful dissection for it is now that the surgeon resects all tissues down to the margin of the external sphincter. This margin is readily identified as described above by observation of the transverse fold or wrinkle that is made visible when the resectoscope is moved in and out and rotated while the area in question is inspected. When the outer margin of safe resection has been delineated throughout its entire circumference, the excision of apical tissue can be carried out as far as this line. The resection is started anteriorly; the instrument is then rotated a successive adjoining fragments of the gland are excised until the ejaculatory ducts and the crumumontanum are reached but these structures are not removed. Although the apex of the adenomatous gland is tapered in form and ends at the triangular ligament it often extends laterally for some distance on this abutment and resection at the apex must extend not only down to the urethral level but also deeper on each side of the midline so as to include the removal of all adenomatous tissue contained within the capsule. This is greatly facilitated by rectal palpation. By employing a systematic approach in the technique of transurethral resection the urologist is enabled to perform a subtotal removal of the prostate

gland and the size of the gland that is removed depends in a large measure on the factors of experience and experience in the performance of the operation. The author cautions that subtotal prostatectomy is essential to the attainment of consistently good results and when this objective cannot be attained by the urologist it would be well to treat the patient by a caudative procedure for the cure of prostatic hyperplasia depends on the extirpation of the gland.

ROBERT O. BARNES, M.D.

Spontaneous Torsion of the Testicle (Torsione spontanea del testicolo) Mario Raffaele, *Arch. Ital. Urol.* 1947 69 73

In a series of 18 cases of spontaneous torsion of the testicle seen between 1935 and 1945 the author found the greatest frequency between the ages 14 and 25.

An acute onset of pain and protrusion of the testis with swelling of the scrotum and a hard testis are significant for the diagnosis of torsion of the testicle. Transillumination and the finding of a serous material with an explorative puncture confirms the diagnosis.

Torsion if left alone will cause atrophy of the testicle. Although spontaneous torsion is rare it is an infrequent occurrence. The vitality of a twisted testicle ranges between 12 and 16 hours. The earlier the intervention the better the prognosis is.

Manual detorsion may be attempted but is a practical measure to resort to surgery as the only way to correct the condition.

ARMANDO C. CORTI, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Contribution to the Study of Eosinophilic Granulomas and Their Relation to Bony Xanthomas (Contribución al estudio del denominado "granuloma eosinofílico" y a sus relaciones con la xantomatosis ósea) Fritz Schafjowicz and Moisés Polak. *Rev. As. méd. argent.*, 1947 61: 318.

The authors maintain that the difficulty in classifying tumors of the reticuloendothelial system resolves into a lack of exact diagnosis, particularly by biopsy which will enable one to determine whether the lesion is inflammatory hyperplastic, or blastomatous whether it is a reticulosarcoma or the relatively benign hyperplasia of the reticulohistiocytes or whether one is dealing with the solitary granuloma of Otani and Ehrlich, the eosinophilic granuloma of Jaffe and Lichtenstein, or a solitary or multiple osseous xanthoma the latter with or without the Schueller Christian syndrome.

After citing the various factors the authors believe that there is no fixed criterion for classifying these lesions. Some consider them independent entities others related conditions. Eight cases are presented. The studies were confirmed by small biopsy specimens in some instances and in others by abundant material obtained from more extensive surgical procedures.

It was concluded that the lesions were remarkably similar and that the histiocytes are capable of forming fibroblasts or giant cells, can store lipoids, or may be accompanied by an eosinophilic reaction. Moreover it was established that there is a relation between histiocytic granuloma, with or without eosinophils the bony xanthoma, with or without the Schueller Christian syndrome, and Letterer-Siwe's disease. The inflammatory factor as causation of these lesions is stressed. Classification of the reticuloendothelial hyperplasia is appended.

STEPHEN A. ZIEGLER M.D.

Functional Aspects of the Abductor Muscles of the Hip Verne T. Inman *J. Bone Surg.* 1947 29: 607

In order to explain the various clinical observations in instances of derangement of the abductor muscles, the authors made a study of the forces acting in and around the hip joint. The reacting force in the head of the femur resists not merely the pressure of the superincumbent body weight, but, in addition the force of the abductor muscles and the tension on the iliotibial tract which is necessary to hold the pelvis in equilibrium. With the knowledge of the direction of the reacting force through the head and neck of the femur against the pelvis the changing angle of the capital epiphysis during growth becomes partially explainable. Close inspection of roent-

genograms of the upper end of the femur in individuals of various ages reveals that the epiphysal line always lies at a right angle to the direction of the medial trabeculae of the femoral neck. Since the reacting force in the femur follows these trabeculae there is no shear on the epiphysal cartilage. The only force to which it is subjected normally is a compressional one. As growth occurs, with increasing length of the femoral neck and increasing angle of pull of the abductor muscles and the fascia, the epiphysal cartilaginous plate rotates so as to lie perpendicular to the equilibrant force in the femoral neck.

The interrelationship of these forces becomes altered in cases of paralysis of the abductor muscles and in congenital dislocation of the hip. In the first instance the loss of muscle power prevents the attainment of equilibrium with the body in a normal position. To prevent the pelvis from rotating toward the nonweightbearing side the individual shifts his center of gravity over the affected hip by bending to that side. The resultant forces acting through the hip become more nearly vertical. The equilibrant or reacting force in the femoral neck likewise shifts toward the vertical; the epiphysal cartilaginous plate remaining perpendicular to these forces continues to be relatively horizontal and coxa valga results. This is a constant finding in individuals who have had paralysis early in life and the degree of coxa valga is in proportion to the loss of muscle power. Coxa valga occurs in individuals suffering from congenital dislocation of the hip for the same factors are at work. In these cases, the loss of fulcrum prevents the normal development of the abducting forces. The load is borne vertically on the femur and the capital epiphysis reacts by remaining horizontal. In malum coxae senilis the bone changes affect predominantly the superior aspect of the femoral head because the forces are concentrated there.

After the magnitude of the torque about the hip joint has been determined as the center of gravity of the body lies medial to the center of rotation of the hip it becomes possible to calculate the minimum pull of the abductor muscles and the amount of tension exercised by the iliotibial tract in counteracting this torque. Since the center of gravity necessarily lies in the median sagittal plane the torque is the product of the body weight and the distance from the median sagittal plane to the center of rotation of the femoral head. The determination of the experimental values of the torque about the hip joint on the weight-bearing side was based upon myographic recordings. Both skin and needle electrodes were utilized. The electrodes were placed in or over the tensor fasciae femoris the gluteus medius, and the gluteus minimus. The action currents were amplified by means of the Grass electroenceph-

At the conclusion of the second phase of operation the surgeon is able to view the entire fossa from the vantage point at the apex of the gland. In the distance he can see the denuded internal sphincter and in the foreground he is able to inspect the smooth concave walls of the prostatic fossa. Bleeding points are readily discovered.

The final phase of operation requires a meticulous and careful dissection for it is now that the surgeon resects all tissues down to the margin of the external sphincter. This margin is readily identified as described above by observation of the transverse fold or wrinkle that is made visible when the resectoscope is moved in and out and rotated while the area in question is inspected. When the outer margin of safe resection has been delineated throughout its entire circumference, the excision of apical tissue can be carried out as far as this line. The resection is started anteriorly; the instrument is then rotated as successive flanking fragments of the gland are excised until the ejaculatory ducts and the verumontanum are reached but these structures are not removed. Although the apex of the adenomatous gland is tapered in form and ends at the triangular ligament it often extends laterally for some distance on this abutment and resection at the apex must extend not only down to the urethral level but also deeper on each side of the midline so as to include the removal of all adenomatous tissue contained within the capsule. This is greatly facilitated by rectal palpation.

By employing a systematic approach in the technique of transurethral resection the urologist is enabled to perform a complete removal of the prostate

gland and the size of the gland that is removed depends in a large measure on the factors of duration and experience in the performance of the operation. The author cautions that subtotal prostatectomy is essential to the attainment of consistently good results and when this objective cannot be attained by the urologist it would be well to treat the patient by a definitive procedure for the cure of prostatic disease depends on the extirpation of the gland.

ROBERT O. BEAN, M.D.

Spontaneous Torsion of the Testicle (Torsione spontanea del testicolo) Mario Ballestrero. *Arch. ital. chir.* 1947 69 23

In a series of 18 cases of spontaneous torsion of the testicle seen between 1935 and 1945 the author found the greatest frequency between the ages of 15 and 17.

An acute onset of pain and prostration of the patient with swelling of the scrotum and a fluctuant mass are significant for the diagnosis of torsion of the testicle. Transillumination and the finding of a serous material with an explorative puncture confirm the diagnosis.

Torsion if left alone will cause atrophy of the testicle. Although spontaneous detorsion is possible it is an infrequent occurrence. The vitality of a twisted testicle ranges between 12 and 16 hours. The earlier the intervention the better the prognosis.

Manual detorsion may be attempted but is not a practical one must resort to surgery as the best way to correct this condition.

ARTHUR F. CIMOLA, M.D.

indics proprius into the tendinous expansion of the first dorsal interosaeus. Action of the extensor pollicis longus may be restored by transplanting the extensor indicis proprius or the extensor carpi radialis brevis (or longus) into the extensor pollicis longus. Transfer proximal to the wrist allows for normal oblique pull of the tendon around Lister's tubercle. A factor in diagnosis of function of the extensor pollicis longus is the ability to extend weakly the distal phalanx of the thumb by use of the extensor pollicis brevis. The authors prefer transfer of the extensor indicis proprius. Loss of action of the abductor pollicis longus and the extensor pollicis brevis may be corrected by transfer of the extensor carpi radialis brevis. The flexor pollicis longus is sometimes the only muscle paralyzed. Transfer of a sublimis tendon to the flexor pollicis longus is the only way to substitute a tendon of equivalent excursion. Transfer above the wrist is advised if the tendon itself is not damaged. Satisfactory function may be obtained by transferring the palmaris longus, flexor carpi radialis, wrist extensors, or the brachioradialis tendon. Occasionally mobility of the metacarpophalangeal joint of the thumb may be limited, and then an osteotomy, bone block, or other procedure should be performed before tendon surgery is considered. In instances of loss of profundus muscle function, satisfactory repair may be obtained by suture of the dysfunctional tendons to active tendons of the same type.

Tendinous reconstruction for permanent paralysis of the radial nerve gives good results. In cases of complete radial nerve palsy the pronator teres insertion is divided and transplanted into the radial wrist extensors. The flexor carpi ulnaris is transplanted into the extensors of the long finger, ring finger and little finger. The flexor carpi radialis is transplanted into the extensor pollicis longus and the extensor of the index finger. The palmaris longus is transplanted into the abductor pollicis longus and the extensor pollicis brevis. In cases of palsy of the dorsal interosaeus nerve only the same procedure is carried out with the exception of the pronator teres transfer. Occasionally, a patient may desire a more stable wrist than that afforded by tendon transplantation; this may be accomplished by wrist fusion after trial of tendon transplantation.

The ulnar nerve supplies most of the intrinsic muscles of the hand, but, unfortunately upon re-generation after physiological interruption or surgical suture, restoration of function of the small muscles does not always occur. A wide range of disability results, from very little interference of hand function to severe clawing of the fingers and loss of adduction of the thumb. If clawing is severe enough to warrant surgery the Bunnell type of sublimis tendon transfer to the extensor aponeurosis gives gratifying results in supple fingers. Transfers for adduction of the thumb were not performed in this series. Abduction of the index finger may be restored by transfer of the extensor indicis proprius.

Median nerve paralysis frequently results in loss of opposition of the thumb. Various procedures were

utilized especially that of subcutaneous transfer of the sublimis of the ring finger. The tendon is isolated at the wrist, severed at its insertion and rerouted under the flexor carpi ulnaris subcutaneously and one slip is inserted into the proximal end of the proximal phalanx and the other into the distal portion of the metacarpal.

Combined injury of the median and ulnar nerves poses a more formidable problem. Each condition must be carefully evaluated and existing functioning tendons transferred to the most important sites. In severe cases, primary arthrodesis of the wrist will allow the 3 wrist extensors to be transferred to the flexor surface for motivation of the thumb and fingers. In addition the brachioradialis tendon may be used. In such cases, preliminary surgery may be necessary to place the thumb in optimum position. Combined median and ulnar nerve injury frequently leads to malposition of the thumb and loss of free movement due to fibrosis. Opposition of the thumb has been partially restored by using the extensor carpi ulnaris as a motor. In cases falling into the ischemic contracture group contractures lead to gross deformity for which only a little can be done.

Brachial plexus injuries also have a wide variation of returning function. Spontaneous recovery or recovery following surgical interference must be evaluated. When maximum recovery is determined to have occurred improvement of function can be obtained by utilizing the principles incorporated previously.

Throughout this report valuable principles are given which must be considered if maximum benefit is to be derived. Excellent diagrams and photographs illustrate the various procedures. This report portrays activity in one army general hospital and reflects work performed at other similar installations.

KEMATH H. SPONKIE, M.D.

FRACTURES AND DISLOCATIONS

The Value of Patellectomy in the Treatment of Fractures of the Patella (*La place de la patellectomie dans le traitement des fractures de la rotule*)
Felix Lagrot and Jean Salasc. *Mém. Acad. chir.*,
Par 1947 73 361

This article is based on 4 recent simple transverse fractures of the patella and 1 old fracture of the patella associated with post traumatic arthritis all of which were treated with patellectomy. The patella was exposed by a longitudinal midline incision and removed by sharp dissection. The wound was then carefully closed layer by layer. No cast or other type of immobilization was used postoperatively. The patient was encouraged to raise his leg actively from the first postoperative day on 5 minutes in every hour. Full extension and flexion to 90 degrees was obtained within the first month after the operation.

The increased use of this rather radical procedure was the result of observations made by many surgeons that the conservative treatment of patellar

alograph and the output was passed through a voltage integrator to facilitate the estimation of the electric potential. The action potential was obtained as the individual bore all his weight on the limb to which the electrodes were applied. The opposite extremity was fixed at the hip and the knee joint sufficiently to clear the floor. The abductors need only be contracted to keep the pelvis level and the degree of contraction was recorded by means of the myograph.

It is quite apparent that when the subject is standing on one extremity with the pelvis level the force which prevents the pelvis from rotating about the supporting hip is not due entirely to muscle pull. A considerable amount of force is contributed by passive tension on the fascia lata and the iliofemoral tract. As the pelvis is depressed toward the non-weight-bearing side the fascial structures become increasingly taut and at some greater and greater degree of tension until a point is reached where little or no muscle contraction is required.

C. FRED GOEDENOW, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES TENDONS ETC.

The Repair of Defects of the Radius with Fibular Bone Grafts. Richard C. Miller and George S. Phalen. *J Bone & Jt Surg* 1947; 29:692.

There are both advantages and disadvantages in the use of fibular grafts. The fibular graft has the advantage of providing considerable stability to the grafted bone. Furthermore the fibula is approximately the same size as the radius so that ultimately, when healing is complete, the normal contour and probably the normal length of the radius have been restored. Finally the use of a fibular graft will avoid the infrequent but not infrequent complication of fracture through the tibial distal end. The primary disadvantage of the fibular graft is a relatively greater degree of density of cortical bone as compared to that of the radius. The osteogenic properties of the fibular graft are therefore not so great as those of a tibial or iliac graft. To offset this disadvantage it has been suggested that the drilling of multiple small holes throughout the graft might increase the vascularity and the rapidity of take. This procedure has not been employed in any of the cases presented.

Over a period of 15 months the author treated 16 patients with fibular bone grafts. In general the fibular grafts were 12 to 18 inches in length. The distal ends of the ulna were not resected in 13 of the 16 cases. In 3 of these 3 cases the radius was resected and consequently been greatly restricted. All of the patients in whom the radius was resected have recovered and have returned to work. The patients in whom the radius was not resected have recovered and have returned to work.

The author states that resection of the distal end of the radius was not indicated in the

graft operation. This procedure eliminated a procedure which would probably be necessary to restore rotation to the forearm and correct the deviation of the hand. In the authors' series there has not been a great deal of difference anatomically or functionally between the cases in which the ulna has been anchored to the distal radius and those in which it has been left free.

The fibular graft is obtained from a central incision preferably that on the side opposite the forearm to give the second surgical team more room in which to work. The fibular shaft is exposed and penetrated through a lateral longitudinal incision dissection being carried down along the posterior intermuscular septum between the peroneal and soleus muscles. Care is taken not to injure the muscles. A measured amount of fibula is then removed with a Gigli saw or osteotome. The length of the graft may be calculated before operation by adding 3 inches to the length of the radial defect. Initially as much of the fibula as desired may be removed; this may if necessary include the ends of the bone. It is, of course, necessary to preserve the peroneal nerve as it rounds the neck of the fibula. Distally at least 3 inches of the fibula must remain to maintain the stability of the ankle mortise. In the forearm it was found best to employ a distal radial incision. The superficial branch of the radial nerve is identified and protected throughout the operation. Dissection is carried down through the musculospiral groove usually between the extensor carpi radialis longus and the brachioradialis and the radial fragment is exposed subperiosteally for a distance of at least 12 inches. Scar tissue and deviated bone fragments are removed from the site of union. The ends of both radial fragments are sawed back at right angles to the shaft until the sclerotic portion has been removed and good vascular bone is apparent. The graft is held in place by metallic fixation. In 15 cases, the distal fragment is so osteoperforated that screws will not hold and in these cases a distal strand of No. 22 tantalum wire has been used.

In this series infection occurred in 2 cases. In one case the purulent drainage had to be continued for 2 weeks after the operation, and in the other case it occurred 8 weeks postoperatively. Penicillin is given 100,000 units for 3 days before operation and both penicillin and sulfadiazine are given for at least 6 or 7 days after operation.

C. FRED GOEDENOW, M.D.

Tendinous Recombination of the Hand Following Irreparable Injury to the Peripheral Nerves and Brachial Plexus. C. A. Lockey and S. R. McPherson. *J Bone & Jt Surg* 1947; 29:570.

Combinations have produced many interesting injuries to nerves of the upper extremity and the hand, as the brachial plexus and the ulnar nerve, and the results have been variable.

Restoration of function of the hand after such injuries is often difficult. At times it is possible to be restored in case of loss of function of the hand by transfer of muscle by transfer of a nerve.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

A Study of the Results of the Surgical Treatment of Varicose Veins. Ross S. McIlwhee Jr., and Bernard Malsel. *Ann Surg* 1947 126 350

The authors have reviewed all of the cases of varicose veins treated by operation at the New York Hospital New York City between 1920 and 1944. They desired to obtain information concerning the physical findings, the operation employed, the duration of hospitalization, the number of postoperative injections required to give satisfactory result and the ultimate outcome.

As indicated by the authors among many competent and experienced surgeons there seems to be no general agreement on the operation offering the best chance of a cure in so common a disorder a variety of operative procedures are rarely to be found in the current reports. The authors point out that the lack of proof that there is any one method which is superior to others in treatment of varicose veins is demonstrated by the simultaneous use of several operative procedures by the surgeons on the three services of the New York Hospital men with the same relative ability and experience. Each service employed one of the three more common operative procedures: (1) high saphenous ligation (2) multiple ligation (3) stripping the vein without regard to the events of the varicosities.

The operations were carried out under local anesthesia and consisted of five types of procedure: (1) high ligation of the internal saphenous vein at its junction with the femoral vein care being taken to divide all collateral and remove a segment of vein (2) procedure No. 1 plus multiple interruption of ligation and division of the vein along its course (3) procedure No. 1 plus extirpation of a portion of the vein by means of a May trapper (4) procedure No. 1 plus retrograde injection of a sclerosing solution into the distal vein and (5) procedure No. 1 plus excision of prominent varicosities which were thigh or calf.

Results in 452 cases of varicose vein surgery during 1 year or more after operation were recorded. High ligation of the saphenous vein combined with multiple ligation or retrograde injection or stripping of the vein have been found to give satisfactory results in between 80 and 90 per cent of the cases. If ligation was longest and the degree of discomfort was greatest following retrograde injection or stripping and was least following high ligation or multiple ligation.

Complications were more frequent after multiple ligation though the majority were not serious. They occurred more often after retrograde injection than after high ligation or stripping. They were also more frequent after stripping than after high ligation or multiple ligation.

grade injection required the smallest number of postoperative sclerosing solution injections to attain satisfactory results.

The authors conclude that multiple ligation (including of course high ligation of the saphenous vein) is the operation of choice.

EDWARD L. LEWISON, M.D.

The Effects on Venous Endothelium of Alterations in Blood Flow Through the Vessels in Vein Walls, and the Possible Relation to Thrombosis. James F. O'Neill. *Ann Surg* 1941 126 250

At the suggestion of Cecil A. Drinker the author undertook the study of spontaneous thrombophlebitis or phlebotrombosis by observing the nutrition of vein walls in specially prepared flat histologic preparations.

Relevant to the etiology of the clinical menace of venous thrombosis the author presupposes that an imbalance between any two of the following factors must exist. These factors are: (a) alteration in the quality or quantity of blood constituents (b) alterations in the rate of flow of blood in the veins and (c) alterations in the endothelial coats of the veins. This paper is devoted principally to a consideration of the last named factor, the vein walls and some of their physiologic relationships.

Venous thrombosis can be produced experimentally by damaging the vein wall in many various ways. This hardly resembles any known pathologic process which may occur in postoperative or postpartum patients or in individuals afflicted with systemic infection, cardiovascular disease or in other debilitating disorders wherein venous thromboses may occur.

Since few investigators have studied the vascular supply to vein walls the author was virtually a pioneer in developing a most ingenious technique for the histologic preparation of flat vein wall segments. The preparation so made allows for careful examination of the vasa venarum and a more exact anatomic description of blood vessel patterns in vein wall. Dilute silver nitrate solution used in staining and studying the inner coats of the vein walls and a benzidine stain is used for outlining the vascular plexus in the vein walls.

Carefully devised experiments were performed to study the effect on the vein wall, principally on the endothelium when the blood supply via the vasa venarum was cut off. Circulation indicated that division of all blood vessels lymphatics and nerves to a given vein segment over a period of one to six hours resulted in increased permeability and edema. This occurred with the preservation of the endothelial part of the wall but the endothelial cells were

EDWARD L. LEWISON, M.D.

fractures, i.e., open reduction and circular wire loop fixation had not been very satisfactory. The post-operative disability lasted for an average of 164 days. Exact apposition of the patellar fragments was rarely possible and the lack of a smoothly gliding even, articular surface gave rise to traumatic arthritis and to permanent limitation of flexion and extension of the knee joint.

Brooke suggested that the patella was not a real element of bone since it developed in tendon and the tendon, but a rudimentary third bone of the leg. He found the patella to be absent in a great number of fast moving animals and concluded that it was not necessary for normal human locomotion. Although very interesting, these observations are of lesser importance in the evaluation of whether or not patellectomy is a good procedure than clinical observations of operated patients.

Schmir pointed out that patellectomy was a short procedure of which the convalescent period was very brief (about 8 weeks) and that it did not decrease the range of motion or stability of the knee.

A more precise analysis of these 3 points showed however that the excision of the patella actually was a rather simple procedure although the repair of the created defect often was difficult and time consuming. Watson Jones recommended an overlapping "bunched" type of repair while MacAusland used fascial strips to repair the defect and Brooke used silk and cotton sutures. Early mobilization of the knee joint does not depend on the type of operation but rather on an intact extensor apparatus of the leg; therefore no objection to mobilizing the knee actively shortly after suture of the fractured patellar fragments. It must also be taken into consideration that the question as to whether or not the results of patellectomy were excellent were not alike in the literature. Bruce, Walmsley and Chou observed that patellectomy in dogs and rabbit eventually caused degenerative arthritis and limitation of motion in the knee joint.

Haxton proved that the patella played an important part in the extension of the leg against resistance. Although the quadriceps of the patellectomized leg did not show any atrophy dynamometric measurements showed a definite weakness compared with the normal extremity. (Quoted from that the re was a loss of strength. The

regeneration of an imperfectly formed, telluric structure of the formation of the knee interfered with the normal function of a tomized knee. Also in the absence of a femoral condyles were entirely correct as to repeated trauma.

Excision of the patella was found to be a comminuted fracture of the bone in case of the suture holding the fractured fragments together and necessitating another operation in which a patellar osteophyte limited motion of the knee joint. Partial patellectomy was done in which the absence of the excised part would not disturb the articulating surface of the tibia. Tanner reported a number of patients in 1911.

The discussion of this paper was continued. He suggested that the wire loop fixation of a transverse fracture of the patella was the method of choice and stated that when it was carried out with care it showed consistently good results. In fact, Somerville had the operation performed with very satisfactory results.

Borrie found that patients treated with wire fixation and who were allowed up for a few days of time eventually showed compensatory arthritis and irregularities of the patella. He reduced the range of flexion in the knee joint. These patients often had to be reoperated on a few days later when performed.

Levinson had excellent results from the use of his teacher Valla. After exact reduction of the patella the fragments were held together by wire hooks which were removed after the lateral ligaments were sutured together with catgut. Motion started after the eighth day. He thought that the absence of a foreign body (wire) favored the end result.

McClary favored the wire loop type of repair for transverse fractures of the patella combined with comminution of the peripatellar fibrous structure.

Mr. McCallum in his closing remarks expressed a feeling that most of the speakers favored the conservative point of view. He agreed with the speakers occasionally the results of the conservative method were not perfect. He felt that the use of a wire loop fixation of the patella was a better method than the use of a wire loop.

certain unless the actual communication are either ligated, extirpated or thrombosed. Of the 3 patients whose cases were reported in the literature and who were treated surgically, only 13 were cured. In 6 instances a direct attack on the involved vessels with excision was successful. Four patients were cured by ligation and division of multiple small fistulas. Only 1 of the cures was effected by ligation of the principal artery leading toward the involved vessels. Reid and McGuire reported a cure of congenital fistula between the external carotid artery and the external jugular vein in which case the artery and vein were ligated and transected the proximal vein then being twisted to occlude the fistula. Ferris Smith reported the cure of an aneurysm in the tympanum in which he ligated the veins and packed the aneurysm.

In 12 of the cases reported in the literature the patient required more than 1 operation to relieve the symptoms partially or totally. In the case presented considerable improvement resulted after 1 operation. The patient was a 6 year old girl who had noted buzzing in her left ear as long as she could remember. There was a swelling below the ear and a pronounced thrill could be felt over the involved area. The murmur could be diminished by pressure over the left common carotid artery but pressure over both common carotid arteries was required to obliterate it. X rays revealed the left half of the mandible to be larger than the right. Angiography with 15 cc of thorotrast injected into the left common carotid artery revealed that the opaque medium went directly into the external artery, avoiding the internal carotid and then into the internal maxillary artery. Here abnormal arteriovenous communication between the latter artery and the vein of the pterygoid plexus could be seen. Since direct attack on the fistula would have involved a dissection and a figuring procedure and since compression of the common carotid arteries had been necessary to stop the murmur which indicated that some blood supply to the fistula was coming from the opposite side it was decided to pack the artery with muscle at the site of the fistula and thus directly occlude the abnormal communication.

At operation a very large pulsating external jugular vein was ligated and transected, then the branches of the external carotid artery proximal to the fistula were ligated and a 5 cm by 3 mm strip of sternomastoid muscle was inserted into the external carotid so as to extend into the area of the fistula. The postoperative course was uneventful and the patient was discharged on the eighth postoperative day. Two and a half months after operation a faint bruit could be heard just in front of the left ear and pressure over the external carotid artery stopped the murmur which indicated that this vessel was now supplying a small opening not occluded by the muscle. The size of the heart has diminished considerably since operation. The operative technique was followed a month after operation with a similar result and no recurrence of the murmur.

A summary of the cases of congenital arteriovenous fistulas of the face and neck reported in the literature is then presented. ROBERT A. NARATOFF, M.D.

Fatality following the Use of Intravenous Ether in the Treatment of Peripheral Vascular Disease
Sydney Sewall *Bull Hosp Joint Dis., N Y* 1947
8: 11.

The author presents a case in which death followed the use of ether intravenously in the treatment of peripheral vascular disease. Postmortem examination revealed numerous pulmonary fat emboli and parenchymatous degeneration of the liver and kidneys. A search of the literature showed that ether was found not to be as harmless as previously believed. In view of the findings the author suggests that cases be well selected before treatment by intravenous injection of ether is undertaken, that liver and renal functions be carefully determined before treatment that these tests be carried out at frequent intervals during the period of treatment and that treatment be immediately discontinued if any impairment of the function of the vital organs is found.

A history of the chemical production of ether is presented. The introduction of its use in medicine and its use for therapeutic purposes is described.

ether was first used intravenously in the treatment of peripheral vascular disease in 1945. Prior to its use intravenously, it was used intramuscularly, but the objection to this method was that ulcers developed at the site of injection. The mechanism of its action is thought to be due to the increased flow of blood in the peripheral vessels caused by the action of ether gas on the small peripheral collateral. In the treatment of peripheral vascular disease a 2 to 4 per cent solution in 1,000 c.c. of sixth molar lactate saline or glucose is given daily for 12 consecutive days. After a rest period of 2 days 12 more daily injections are given.

The author presents a case in which ether was used in the manner described. The patient was a 53 year old negro female who had an ulcerating arteriosclerosis of both lower extremities. Amputation of the fifth toe because of gangrene was followed by ulceration at the site of amputation. A 25 percent solution of ether and dextrose was given intravenously for 12 days. After a 2 day rest period treatments were again resumed. With this treatment the patient improved generally and locally. She experienced a sense of warmth in both lower extremities and a feeling of well being. Healthy granulation tissue began to appear in the wound. On the third day of the second course the patient developed a shaking chill followed by an elevated temperature. The treatment was stopped and on the morning of the second day after cessation of treatment the patient had a 10 centimeter examination of the liver was found to be extremely small and practically crumpled when handled. Microscopic examination of a biopsy specimen gave a picture of pure chrymatocytic hepatitis. The post mortem examination was revealing in that it showed the characteristic changes in the liver.

ing if the red corpuscles of the donor have been destroyed or are still present in the recipient's blood. The authors call this differential agglutination.

A case is described in which violent hemolytic reactions occurred after a series of transfusions. These reactions were explained by the presence in the patient a serum of an abnormal univalent isoantibody unrelated to groups A B O types M N or types Rh or Hr.

The blood factor has been given the provisional designation of SI. The agglutininogen has been found in the blood of 19 of 148 Caucasians tested and it seems to be inherited as a simple dominant mendelian factor.

THEODORE B. MAXWELL, M D

Peritoneal Irrigation for Acute Renal Damage following Incompatible Blood Transfusion: A Discussion Based on 3 Cases. E. E. Muirhead, A. B. Small, A. E. Haley and J. M. Hill. *J Lab Clin M.*, 1947 32 988.

The authors stated that peritoneal irrigation used for the treatment of patients suffering from renal insufficiency following incompatible blood transfusion clears substantial quantities of urea and presumably other waste products from the body. However they believe that the use of crystalloid solution for irrigation appears to be related to 2 major complications, namely the accentuation of acidosis and the absorption of water and salts from the peritoneum. These complications are considered to be deleterious to the progress of these patients during the phase of renal insufficiency and they may retard the onset of diuresis. Muirhead, Small, Haley and Hill have suggested a three-phase regime which seems to oppose these complications. They divided the clinical course of patients experiencing incompatible blood transfusions into (1) hemolysis and hypotension which are characterized by a sudden onset with apprehen-

sion, tightness in the chest, backache, dyspnea, cyanosis and mental confusion, hypotension, chills and fever and hemoglobinemia, hemoglobinuria. (2) renal insufficiency which is attended by oliguria, blood casts in the urine, hypertension, azotemia, altered chemical pattern of blood (mainly depressed serum sodium, calcium, blood chloride concentration and carbon dioxide combining power of plasma) and mounting antibody titer and (3) copious diuresis which is accompanied by marked water salt loss from the body. Each phase requires its own distinctive type of management.

During the first phase blood transfusion of undoubted compatibility should be given to cope with anemia and lowered blood volume, thus decreasing the period of hypotension.

During the second phase, forcing fluids appears deleterious because the kidneys are not in a position to handle water and salts. The best results during this period have been obtained by restricting the fluid intake to a conservative estimated insensible loss plus the scanty urinary output (a total usually of from 800 to 1,500 ml. daily for from 6 to 8 days). A high caloric low salt formula is given with this fluid plus water soluble vitamins. Sodium bicarbonate in doses of from 4 to 6 gm. is given daily to cope with an excessive lowering of the carbon dioxide combining power of the plasma. This regime is based on the premise that damaged kidneys require time for healing. When the diuresis appears the water salt loss through this means is replaced. Such losses may require from 20 to 40 gm. of salts daily plus from 5,000 to 10,000 ml. of water. As soon as possible the patient is allowed to adjust his own intake and output.

It has been the experience of the authors that when patients are overloaded with water and salt they die or the onset of diuresis is delayed.

ROBERT TURNER, M D

The author presents a brief review of the toxic effects of ether. He notes that Mann (5) in 1926 showed that ether produced demonstrable effects on hepatic activity. The capacity of the liver to store glycogen is also disturbed by ether. The liver under ordinary circumstances converts lactic acid to glycogen but during ether anesthesia it does not seem able to do this and the liver glycogen is depleted.

HENRY F. TUCKER, M.D.

Functional Survival of Autogenous and Homogenous Transplants of Blood Vessels. An Experimental Study. Carl S. Williamson and Frank C. Mann. *Arch. Surg.* 1927 54: 529.

A series of 6 medium-sized dogs were selected at random. This group of animals was divided into 3 pairs so that both an animal in each pair would act both as a donor and a recipient. With the animals under ether anesthesia and with the use of aseptic technique sections from the carotid artery and the jugular vein of each animal were removed and exchanged for similar sections removed from the same vessels of the other member of the pair.

Of the 12 transplants, 6 were arterial transplants and 6 arterial transplants resulted in no lumen after an elapsed time of 36 to 63 days. In the arterial transplant, no lumen will be developed until the time of removal, and the other lumen could not be determined grossly, but a limited degree of lumen was observed by histological examination. All the venous transplants had ceased to function at the time of removal and the remaining arterial transplants had also ceased to function. The results in 1 of the animal was compromised by a severe postoperative infection. Grossly there was nothing to account for the failure of the vascular transplant to survive. The histologic picture in both the arteries and the veins was well but was consistent in some respects in all the specimens.

The most common histologic picture in all thrombotic arteries is in the tendency toward vascularization in the thrombus which occluded the lumen of the vessel. The vascularization included the walls of the vessels themselves. These newly formed blood vessels were fairly large in some instances and were evidently serving as conduits for a small amount of blood in both the arterial and the venous transplants. The thrombi which were present in the arterial transplants had a poorer appearance, some of them but those in the veins were more well organized and there was a coiled tendency of the blood vessel into segments by cross-section.

The distribution of the arteries was less regular than the veins and there was a greater tendency toward canalization of the thrombi. In general, the arteries had a fairly well prepared lumen, but it has been largely determined that the lumen of the vessel is not the same as the lumen of the normal vessel in number and size of the blood vessels in the vessel itself.

fibers and much of the elastic tissue is replaced by fibrous tissue. In summary, it is shown that the structure of the arterial and the venous segments of vessels had not been damaged except in a few instances.

Uniformly the destructive process in the walls of the transplanted veins was complete. The veins were thrombosed and, while there was a tendency toward vascularization, the process was not pronounced. The thrombi were more solidly organized and seemed to be attached to the wall of the vein than to the arterial transplants. The venous segments were for the most part well preserved. There was extensive replacement of the normal structures with fibrous tissue and, therefore, this replacement was almost complete. Attention of the severity of the reaction in the veins was obvious. In all the transplants, the arterial transplants, there was a tendency toward vascularization of the walls of the vessels as well as of the thrombi which occluded the lumen. The character of the most pronounced in the arterial transplants was in the thrombi. This led by the time of the removal to be considerably different from the arterial circulation. The status of the transplants in relation to the ultimate survival of the transplants is a problem for future investigation.

The author emphasizes the following points: 1. The technique of vascular transplants is established and the surgeon who is able to perform the requirement necessary for success can expect satisfactory end results in the transplants. 2. The autogenous transplant method is a feasible surgical procedure in the light of present knowledge.

3. Homogenous transplants in the arteries as well as of other body structures are not in the light of present knowledge.

4. There is a striking tendency for thrombi to develop in both the thrombus and the wall of the vessel in homogenous vascular transplants. This is the most conspicuous in the arterial transplants.

BLOOD TRANSFUSION

Hemolytic Intra-group Transfusion Reaction Due to a Hemagglutinating not Hitherto Described (Reaction) in the Blood of Guinea Pigs. Due to A. B. Bernard and J. G. J. van der Vliet. *Arch. Intern. Med.* 1927 53: 3.

Although a percentage of intra-group reactions is avoided by testing for the Rh factor, it is still a question whether a child or an adult is Rh positive or Rh negative and hemolytic or non-hemolytic due to other non-specific agents. These reactions themselves are of a gradual set in after hemolytic reaction. The reaction is not a usual one and is not after hemolytic reaction. It is a rather available laboratory test for diagnosis of the blood group.

ing if the red corpuscles of the donor have been destroyed or are still present in the recipient's blood. The authors call this differential agglutination.

A case is described in which violent hemolytic reactions occurred after a series of transfusions. These reactions were explained by the presence in the patient's serum of an abnormal univalent isoantibody unrelated to groups A, B, O, types M, N or types Rh or Hr.

The blood factor has been given the provisional designation of SL. The agglutininogen has been found in the blood of 19 of 148 Caucasians tested and it seems to be inherited as a simple dominant mendelian factor.

THEODORE B. MARSHALL, M.D.

Peritoneal Irrigation for Acute Renal Damage Following Incompatible Blood Transfusion: A Discussion Based on 3 Cases. E. E. Muirhead, A. B. Small, A. E. Haley and J. M. Hill. *J. Lab. Clin. Med.*, 1947, 32, 983.

The authors stated that peritoneal irrigation used for the treatment of patients suffering from renal insufficiency following incompatible blood transfusion clears substantial quantities of urea and presumably other waste products from the body. However they believe that the use of crystalloid solution for irrigation appears to be related to 2 major complications, namely the accentuation of acidosis and the absorption of water and salts from the peritoneum. These complications are considered to be deleterious to the progress of these patients during the phase of renal insufficiency and they may retard the onset of diuresis. Muirhead, Small, Haley and Hill have suggested a "three-phase" regime which seems to oppose these complications. They divided the clinical course of patients experiencing incompatible blood transfusions into (1) hemolysis and hypotension which are characterized by a sudden onset with apprehen-

sion, tightness in the chest, backache, dyspnea, cyanosis and mental confusion, hypotension, chills and fever and hemoglobinemia-hemoglobinuria; (2) renal insufficiency which is attended by oliguria, blood casts in the urine, hypertension, azotemia, altered chemical pattern of blood (mainly depressed serum sodium, calcium, blood chloride concentration and carbon dioxide combining power of plasma) and mounting antibody titer and (3) copious diuresis which is accompanied by marked water salt loss from the body. Each phase requires its own distinctive type of management.

During the first phase blood transfusion of undoubted compatibility should be given to cope with anemia and lowered blood volume thus decreasing the period of hypotension.

During the second phase, forcing fluids appears deleterious because the kidneys are not in a position to handle water and salts. The best results during this period have been obtained by restricting the fluid intake to a conservative estimated insensible loss plus the scanty urinary output (a total usually of from 800 to 1,500 ml. daily for from 6 to 8 days). A high caloric, low salt formula is given with this fluid plus water soluble vitamins. Sodium bicarbonate in doses of from 4 to 6 gm. is given daily to cope with an excessive lowering of the carbon dioxide combining power of the plasma. This regime is based on the premise that damaged kidneys require time for healing. When the diuresis appears the water salt loss through this means is replaced. Such losses may require from 20 to 40 gm. of salts daily plus from 5,000 to 10,000 ml. of water. As soon as possible the patient is allowed to adjust his own intake and output.

It has been the experience of the authors that when patients are overloaded with water and salt they die or the onset of diuresis is delayed.

ROBERT TITCHELL, M.D.

SURGICAL TECHNIQUE

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Bone Abscess from Human Bite A. T. Andreasen.
Fed J S 1 191 34 4 1

The author reports a case of bone abscess arising from a human bite. This is the only case in the literature. A 21 year old army officer was bitten at the base of the right index finger by an enemy soldier. The bone was exposed and the soft parts were badly torn. The wound became badly infected but healed in 2 weeks with good return of function. However the patient was troubled with a highly tender painful swelling over the palmar aspect of the metacarpal bone.

Several weeks later the wound area began to swell and became more inflamed. It became red and swollen. There was considerable edema of the dorsum of the hand. An abscess and marked tenderness over the metacarpal head appeared. After drainage the wound rapidly healed. The organisms were hemolytic staphylococci and fusiform bacilli of the type seen in Vincent's angina.

Some weeks later a diffuse swelling of the same region appeared and the patient complained of aching. A fluctuant swelling was noted. On x-ray examination a clear area of abscess with considerable periosteal reaction about them were seen in the heads of the second and third metacarpals. The hand was immobilized in plaster for 2 months to allow the swelling to subside.

After preoperative ulnar and brachial plexus block anesthesia an incision was made along the radial wrist of the dorsal aspect of the second metacarpal from 1 cm. above the metacarpophalangeal joint to 1 cm. proximal to the base of the bone. The superficial fascia was incised in the line of the incision. The incision through the deep fascia was so placed as to leave the compartment containing the tendons intact. The incision was then carried down to bone through the periosteum on the radial edge of the 2nd metacarpal. The periosteum was elevated. With a fine matrigue the abscess was exposed. After a check was made with a methylene blue test the abscess was opened carefully. The abscess was then drained. The periosteum was sutured over the bone. The skin was sutured in the hair placed on a wet paper to replace the lost finger in position. At the metacarpophalangeal joint the wound was closed by primary union. There was only slight residual swelling. The bone abscess and the abscess of the soft parts were cured.

Apparently the abscess deepened in the first few weeks after the bite. There was a local abscess formation which was drained. The abscess was treated with a 1% solution of the unexcavated bone. The abscess opened again several times but did not recur.

The author recommends the deep edge of the incision in approaching the second metacarpal. A good access and does not disturb the flexor tendons around the extensor tendons. He points out that superficial fascia often may consist of a firm. Recognition of this is important to avoid unnecessary stripping up of the wrong fascial layer.

An arrangement is described by which a drain can be taken during the operation procedure. It is of value in a hand and forearm. It is of value in a joint space.

The author uses a wooden block beneath the surface of the hand during surgery to support the hand.

Meticulous asepsis is well worth the additional care required.

Rehabilitation has been largely responsible for better functional results following the treatment of hand injuries and infections.

ROBERT R. DUNN, M.D.

Caronamide and Penicillin. J. William Orsow, William P. Dodge, Carl Joseph C. Orsow and A. Katharine Miller. J. Am. Med. Ass. 1943 133 13

The authors studied a new drug, caronamide (4-carboxyphenylmethanesulfonamide) when administered by mouth to patients receiving penicillin. Caronamide produces a physiological and biochemical inhibition of the excretion of this antibiotic. In elevation of the concentration of penicillin in plasma. With the aid of caronamide it is possible to maintain a high plasma concentration of penicillin in the treatment of resistant infections.

Normally about 80 per cent of penicillin in urine is excreted by the renal tubules and is maintained 20 per cent by glomerular filtration. It has been known that penicillin and para-aminobenzoic acid which are excreted by the renal tubules inhibit the excretion of penicillin. These drugs act on the active transport mechanism of the renal tubules and thus inhibit the excretion of penicillin. Caronamide on the basis of chemical structure is found to be capable of producing a marked inhibition of penicillin excretion. The effectiveness of this drug depends on its competitive inhibition of penicillin excretion. The tubules and a causal relationship is shown by that transport mechanism.

In this low test in a patient receiving penicillin while receiving caronamide the excretion of penicillin was increased. The excretion of penicillin was increased by the administration of caronamide. The excretion of penicillin was increased by the administration of caronamide. The excretion of penicillin was increased by the administration of caronamide.

to 7 times those observed during the control periods. Buffering agents were not administered with the penicillin, the patients were allowed to take fluids freely, meals were given in accordance with hospital routine and no effort was made to enhance the penicillin levels apart from the administration of caronamide.

Another group of 8 patients were given penicillin intramuscularly and caronamide orally in varying dosages. Five of these patients given either 1 gm. of caronamide every 3 hours or 2 gm. every 4 hours showed an increase of the penicillin plasma levels of from 2 to 7 times those observed during the control periods. Three patients given only 1 gm. of caronamide every 2 hours failed to show the same degree of increase of penicillin concentrations.

Six patients receiving penicillin in beeswax and oil (Romanovsky formula) and oral caronamide also showed an increase in penicillin plasma concentrations while 3 other patients yielded equivocal results. This phase of the investigation has thus far been incompletely studied.

This clinical investigation suggests that from two-fold to sevenfold increase of penicillin plasma concentration may be expected if about 2 gm. of caronamide are administered concomitantly with penicillin (given orally or parenterally) every 3 and 4 hours respectively. Thus far no systemic toxicity was noted in the patients who received caronamide. This drug promises great therapeutic usefulness in the treatment of lesions which require high penicillin concentrations.

ROBERT TUKELL, M.D.

Anuria Observed in Connection with Penicillin Therapy

Bengt Nylen *Acta chir scand* 1947
95 483

Reports in the literature on toxic reactions in penicillin therapy with special regard to the kidneys are reviewed and the author presents a case of anuria which probably resulted from toxic effects of penicillin on the kidneys. In an experimental investigation on rats he found that the penicillin used had no diuresis inhibiting effect on animals with damaged kidneys.

Minor transient rises of the nonprotein nitrogen have been reported in penicillin therapy but albuminuria or other signs of renal damage were lacking. It has been found that penicillin is excreted for the most part through the tubules. When renal function is impaired penicillin is excreted more slowly and to a lesser extent and the penicillin level in the blood is higher than in normal cases. Anuria has been reported in a case of acute meningitis treated with sulfamerazine and penicillin and has been produced experimentally in rabbits by the injection of large doses of penicillin. The reactions observed in penicillin therapy are generally attributed to impurities in the penicillin.

In order to determine whether penicillin, in the case of damaged kidneys, has any effect on diuresis the following experiment was performed. The left kidney was removed from a group of male rats and 3

weeks later the upper and lower poles of the right kidney were removed. Control animals were killed immediately after the second operation and the remainder of the kidneys was removed and weighed for comparison with the amount of renal substance in the experimental animals. After about 1 month the experimental animals were placed in cages where the urine could be collected, measured and tested for albumin daily. Water intake and weight were also recorded. These animals were then divided into two groups, one group of which received daily intramuscular injections of penicillin in 6 divided doses for 4 days. Six days later the animals were killed and the kidneys were weighed and prepared for histologic examination. Urea nitrogen determinations were made before, during and after the test.

In these tests the experimental animals showed no difference from the controls in regard to the amount of urine after the injection of penicillin for 4 days nor was there any observable difference between the experimental animals and controls with regard to weight, albumin reaction, urea nitrogen and histologic examination. According to this experiment it seems that penicillin injection in rats whose kidneys have been damaged causes no inhibitory effect on diuresis. The purity of the penicillin used in the experiments was about 1,300 Oxford units per mgm. This penicillin was considerably purer than the penicillin used in the clinical case. The purity of the penicillin may account for the negative result in the experimental test.

JOHN L. LINQVIST, M.D.

ANESTHESIA

Spinal Fluid Findings in Spinal Anesthesia. M. Gene Black. *Anesthesiology* 1947 8 382

A study of the spinal fluid in 200 patients was made to determine the effect of spinal anesthesia. The controls consisted of 75 patients who had no previous record of spinal anesthesia. The spinal fluids taken preoperatively were within normal limits. In 60 cases in which the fluid was taken from 30 days to 10 years after the spinal anesthesia, there was in comparison a mild increase in protein chiefly because the interval was less than 3 months in 30 cases. In 25 cases specimens of spinal fluid obtained before and after continuous spinal anesthesia were examined. Protein variations were negligible which suggests that the time interval was inadequate for meningeal or tissue irritation to be demonstrated. The spinal fluid sugar in this group presents a marked rise at the end of operation when the patient was kept in the horizontal position.

Pontocaine and glucose were the agents used in this study. It is thought probable that the rise in spinal fluid sugar was caused by pooling of the glucose at the site of injection. The Trendelenburg position promotes diffusion and it is believed that diffused glucose promotes the metabolism of the central nervous system.

It is suggested that pontocaine or any similar anesthetic agent used intraspinally may produce

transient irritation in the possible exception occurring in the rare individual who is allergic to the drug (glucose when used in conjunction with spinal anesthetic agents and if permitted to diffuse by use of the Trendelenburg position may be helpful rather than harmful to the function of the central nervous system.

MARY FRANCES FORBES

Discussion on Further Experiences with Curare
Frederick Prescott, Geoffrey Organe, Barnett
Mallinson, John Gillies and Others. *F&R*
Dec 31, Lond., 1947 40-593.

FREDERICK PRESCOTT gives us a picture of the clinical pharmacology of curare. Curare is a crude material totally unfit for clinical use. Clinically the only alkaloid preparation that resists the tubocurarine chloride. In clinical uses this drug has no action other than that of paralyzing skeletal muscle by blocking conduction at the myoneural junction.

Ditubocurarine chloride belongs to the quaternary ammonium salt compound. In man the muscles are affected after curarization in the order of their phylogeny, i.e. muscles supplied by the cranial nerves first, then those of the limbs, back, abdomen, intercostal region, and finally those of the diaphragm.

Epinephrine is said to potentiate the action of prostigmine, which is the antagonist of curarizing drugs. Its effect has not been confirmed in man. It is necessary to give atropine when prostigmine is used to prevent the stimulation of curarization on the parasympathetic nervous system.

Curarelike drugs form a block at the myoneural junction possibly by combining with the receptor substance in the muscle. They do not interfere with the product of L-acetylcholine.

Experimentally the view now held that curariform drugs act in the same way as acetylcholine, i.e. as a chemical mediator.

The curariform action of ether was noted a far back as 1804, but that in high blood concentration has the same effect.

The experimental work of Smith and others has shown that ditubocurarine is a significant central stimulant, depressant, or analgesic, etc. in man. Collins found that the total ionization dose of ditubocurarine is 0.5 mg per kg body weight.

It is curariform in its action on the ear, larynx, and trachea.

Collins and Higgs describe the form of the heart muscle which lies in the trachea in the case of curariform drugs. They state that the heart is a very sensitive organ and that the use of ditubocurarine as a drug is small.

Collins and Cullen believe that ditubocurarine causes relaxation of the smooth muscle of the small intestine but that it does not appear to be contracted. It is a useful agent for the treatment of the small intestine.

The fact that ditubocurarine is a paralytic agent is well known.

low a limitation is an intravenous injection of a satisfactory and this fact has been confirmed by a volunteer.

Both of these drugs produce salivation. For this reason patients should be intubated before using ditubocurarine or intubation.

GEORGE ORGANE describes his experience with ditubocurarine. Case records were shown showing that the results of using ditubocurarine in these cases are not always all that could be desired. The author and Prescott did the first experiments on the preparation known as tubarine at 1942. He believes that although it is useful in the early clinical report, it is not without its drawbacks. Among the 86 patients but only abdominal operations there were 24 with major and 15 with minor chest complications. All are competent and techniques were involved in the first complications. One patient died of bronchopneumonia, 1 of the original disease and 1 was later to have bronchiectasis. The others appeared to have recovered at the time of their discharge but not delayed in any case.

Tubarine has been valuable in the relief of dyspnea, but does not always prevent it. Case reports are presented.

Organe believes that tubarine is a valuable agent in bronchoscopy and esophagoscopy, while it is true that alone they are dangerous procedures because of the difficulty of maintaining a clear airway. If tubarine is used the airway remains clear. His patient breathes quietly. A respiratory is a common accompaniment of severe dyspnea, but the anesthetic agent, but if much less common, if tubarine is used. This author has his own experience emphasizing that one must not neglect none of the precautions in using tubarine.

BARNETT MALLINSON gives some general aspects of the technique of curarization. One of the most significant aspects of the advent of curarization is that it can reduce the number of spinal anesthetic administrations. Curare can be given in the first place or sometimes in the first place with a general anesthetic first place anesthetic usually a general anesthetic can be of a lighter plane. There is no danger of the first place anesthetic.

The author has found the use of curare as a pre-anesthetic that for laryngeal intubation is very useful and prevents the usual large doses of ether or chloroform under a very comfortable condition.

A. C. JONES describes Curare as a useful agent in the treatment of the small intestine. The author believes that curare is a useful agent in the treatment of the small intestine, but if the curarization is sufficient, it is not a useful agent in the treatment of the small intestine. In this case, the author is not sure of the results of the treatment of the small intestine.

JOHN GILLIES. The use of curare in the treatment of the small intestine is well known. It is a useful agent in the treatment of the small intestine, but if the curarization is sufficient, it is not a useful agent in the treatment of the small intestine.

JOHN HALTON People who use curare must learn that it is not enough that the patient is just breathing. The respiration must be aided from the moment of the injection until the curare effect has passed off.

L. C. MOUNTFORD expresses the opinion that the larynx and trachea should be cannalized prior to the use of either curare or pentothal for intubating the trachea.

H. B. WILSON discussed a series of cases in which myanesthesia was used.

MASSEY DAWKINS In a series of 300 patients anesthetized with curare the mortality rate was about 12 times greater than that following the use of chloroform.

CECIL GRAY The 3 main dangers of tubocurarine appear to be its use by the inexperienced and the occurrence of regurgitation of the stomach contents. There is an insidious flowback of the stomach contents due to the abdominal relaxation of the esophageal muscle and sphincter. EDITH EASON M.D.

Resuscitation of the Heart in Anesthetic Syncope
(A propos de la ranimation du coeur dans les syncope anesthésiques) R. Desmarest, J. Lhermitte and G. Jacquot. *Anesthésie Par* 1939, 5: 481.

The authors discuss in great detail a case of anesthetic syncope which occurred at the final stage of a hysterectomy performed under nitrous oxide anesthesia. After artificial respiration and the intracardial injection of adrenalin had been unsuccessful the surgeon severed the sutures of the abdominal wall and performed massage of the heart from the abdominal cavity through the diaphragm. Five minutes after the beginning of the massage the heart started contracting again, and a little later spontaneous respiration set in. Only much later the pupils which had been in maximal dilatation came back to normal. The patient died 64 hours after the accident without having regained consciousness.

During these 2 1/2 days the patient developed signs of severe cerebral irritation: general tetanic convulsions which occurred every 30 to 40 minutes; hyperpyrexia, the positive Babinski sign and hypertension of 200 mm.

The histologic examination of the brain revealed extreme damage caused by anoxia during the arrest of the circulation. The foremost finding was widespread lipid degeneration. This degeneration involved practically every cell of the cerebral cortex also the endothelium of the blood vessels in this region and the adventitia of the precapillaries showed numerous lipid droplets. In the striate body and in the cerebellum the lipid degeneration was less marked whereas the white matter and the gray cells of the medulla did not show any trace of lipid degeneration.

Slides stained according to Nissl revealed karyolysis in the pyramidal cells, hyaline degeneration, fibrillolysis, chromolysis and other degenerative signs which are described in great detail. The neuroglia, especially in the frontal lobe presented signs of proliferation and hyperplasia.

A review of the literature shows that about 100 cases are on record in which massage of the heart was done in anesthesia accidents. In 25 it was successful. Several of these cases showed the same course as the present case: survival for 2 or 3 days after the successful massage of the heart and death under the signs of severe brain damage. On the other hand there were cases reported in which heart action and respiration had stopped for as much as 15 minutes before heart massage was successful without leaving any signs whatever of brain damage.

The authors attach special prognostic importance to the condition of the pupils. They believe that total mydriasis of longer duration is a sign of damage done to the ciliospinal center which gives a poor prognosis even when the circulation and respiration have been restored. WERNER M. SOLMITS M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGEOLOGY

Radiologic Survey of the Salivary Glands (Estado radiológico de las glándulas salivares) Raúl Leborgne, M.D. (Luzern 1924) 535

The radiograph of the salivary gland is done with plain roentgenism and by the latter with the injection of an opaque medium. The roentgenogram of the parotid gland and a series of small nodules is necessary to use with the opaque medium. The lateral roentgenogram of the parotid gland is three fourths of the whole. The lateral roentgenogram of the parotid gland is three fourths of the whole. The lateral roentgenogram of the parotid gland is three fourths of the whole.

The anterior view of the parotid gland is the most useful. The anterior view of the parotid gland is the most useful. The anterior view of the parotid gland is the most useful.

The parotid gland is the most useful. The parotid gland is the most useful. The parotid gland is the most useful.

The parotid gland is the most useful. The parotid gland is the most useful. The parotid gland is the most useful.

the gland. The opaque medium is in the gland for several days.

Cystic basilar adenitis and metastatic carcinoma similar to mixed tumors. Carcinoma produces stenosis of the salivary ducts. The parotid gland is the most useful.

FRANK P. FORTNUM, M.D.

The Technique of Direct (Percutaneous) Contrast Angiography E. Lindgren, Prof. J. J. 1924

The technique of direct needle puncture of the carotid artery for central angiography compared with the open operation method. The former is considered as the more reliable.

The opaque media used by the author are the first injection is 35 per cent iodine solution. The second injection is 50 per cent iodine solution. The third injection is 50 per cent iodine solution.

The puncture is made under 1 per cent ether anesthesia with the patient supine. The puncture is made under 1 per cent ether anesthesia with the patient supine.

The author avoids puncturing the common carotid artery because of the greater dilution of the dye shadows of the external carotid artery.

It will strike the internal carotid artery preferred. Between internal carotid and external carotid arteries.

It causes a burning or smart sensation in the jaw and around the ear. The patient is in a sitting position.

Once the puncture is made the contrast medium is injected. The patient is in a sitting position.

PHYSICO-CHEMICAL METHODS IN SURGERY

193

castets can be changed showing the capillary and venous systems respectively. The roentgen tube is adjusted to the other position, a second injection is made, and three more films are exposed as described. This system was employed in 153 cases and only 4 unsuccessful examinations resulted.

ARTHUR W. PAYNE, M.D.
LEO G. RIGLER and THOMAS B. MERNER
Am J Roent 1947 58 367

Planigraphy in the Diagnosis of Bronchogenic Carcinoma. Recent publications show that bronchogenic carcinoma is increasing in frequency both absolutely and in proportion to other types of malignant neoplasms.

Among the various methods used for diagnosis bronchoscopy occupies first place especially since it provides a means of biopsy. The poor condition of the patient, however, sometimes prevents its use. In other instances especially when the carcinoma is localized to the upper lobe bronchi or when there is a distortion of the bronchi due to extrinsic lesions bronchoscopy is disappointing.

Great progress has been made lately in the roentgen study of the bronchogenic carcinoma. The diagnostic signs may be the result of secondary manifestations of carcinoma or of the primary appearance of the lesion.

The secondary manifestations are due to a gradual obstruction of the bronchial lumen by the carcinoma. Westermarck described three stages in the development of the obstruction. In the first stage there is diminished air content of the segment of the lung involved because of diminished intra alveolar pressure and hyperemia. In the second stage the increasing mass produces a check valve effect resulting in complete obstruction and atelectasis. Fluoroscopy and roentgenograms taken in the maximum of expiration and inspiration, will help most in demonstrating the various phases of the obstruction.

The primary signs of the carcinoma are a mass either in the hilar region or less commonly in the periphery a localized infiltrative process or a diffusion into the affected bronchi of definite value in further identifying the process. With the exception of bronchoscopy it is the most useful method of examination. There are however certain contraindications most important of which are severe dyspnea fever toxicity and uncontrollable cough.

Planigraphy which is also called tomography or laminaography is a more recent method for the diagnosis of bronchogenic carcinoma. It consists of a special attachment to the roentgen tube which holds the roentgen tube to move in opposite directions in one plane around a point of rotation which represents the desired depth. A trial exposure is made usually at about 10 cm. from the table top with the patient in supine position. Additional films are taken at 8 and 12 cm. from the table top and so

on until the clearest image of the lesion has been obtained. It is also advisable to make a film 1 cm. anterior and another film 1 cm. posterior to the level giving the most information about the lesion. In order to obtain parallel plane films in some instances it will be necessary to make the exposures in lateral or oblique views in respect to the patient's body.

Important planigraphic signs are the demonstration of an actual defect within the bronchus the visualization of the bronchus resembling a 'rat tail' and the showing of collateral evidence afforded by the secondary lung changes. For example a clear cut intrabronchial mass is more indicative of benign adenoma of the bronchus whereas if there is a rat tail deformity with surrounding infiltration or a telescopic carcinoma must be suspected.

Planigraphy serves as a supplement to or as a substitute for bronchoscopy. It is not intended however to replace the older methods of examination.

The authors used planigraphy in 181 patients suspected of pulmonary disease. Bronchial tumors were found to be present in 47 patients and in 10 of these a diagnosis of benign adenoma was made. The remaining 37 tumors were bronchial carcinomas as indicated by the collateral findings. Failures were noted in only 5 cases.

The authors present the planigrams with corresponding diagrams in several illustrative cases. The conclusion is reached that the accuracy of planigraphy compares favorably with other roentgen methods of examination and if the technique of application continues to improve it may even reduce the importance of some of the methods now in use.

T. LEVOTTA, M.D.
On Spontaneous Chronic Intestinal Invagination in Adults. P. Bjerre Hansen. *Acta radiol* Stockh. 1947 18 115

Although the occurrence of spontaneous intussusception of the intestine has often been described in children, it seldom has been described in adults. Diagnosis in most instances has been made by means of a barium enema. However the author describes 3 cases of intussusception in which the diagnosis was made by means of a contrast enema and barium meal. Although this procedure is not a new one, the author believes it has not been used frequently enough.

Pertinent roentgen findings may be divided into two groups those visualized by means of a contrast enema and those visualized by means of an oral barium meal.

1. The enema film reveals
2. Abrupt, smooth stop of the barium.
3. Bicornate configuration
4. Partial filling of the invagination sheath in ring shaped stripes, corresponding to the haustra, across the intussusceptum
5. Filling of the colon but with a central stripe like clearing

Fig. 1 (H. von) Distinct invagination is seen just at the flexure of the sigmoid both in the anteroposterior and the lateral views. The invagination is not palpable. The patient is a 45-year-old woman.

Fig. 2 (H. von) Distal part of the sigmoid colon.

The Roentgenologic Diagnosis of Appendical Calculi
 (Benjamin F. Lyon and L. M. F. in Bernburg
Radiology 1931 25 123)

This article is based on 100 cases collected from the literature and 10 personal cases. The latter are briefly described and illustrated with roentgenograms. The usual roentgen signs in 10 of the 10 cases of invagination was diagnosed from the roentgenograms and in 7 patients were operated on. The diagnosis was verified.

A review of the available literature leads to the following fact:

Incidence. Some estimates are given of appendical calculi occurrences. On the other hand, Stern and others consider and to cause appendicitis. The author 10 cases were estimated a total of 300 appendicitis cases.

Findings. There is no fault in the literature as to the effect that appendical calculi are found in the ileocecal junction. According to Kell and others, who offer the most plausible theory of the return of the feculent contents from the appendix, it occurs in invagination in patients of advanced age. This in turn causes a low grade catarrh of inflammation with its attendant secretion of inorganic salts, not in the mucosa are deposited on the surface of the invaginated part of the appendix. The process in invagination is not in the calculi. There is a small percentage with an incidence of 10 percent in patients.

Clinical signs. Of 60 patients who were operated on, 47 were males and 13 were females. There is no characteristic clinical symptom of invagination of the appendix.

Prognosis. The diagnosis of invagination of the appendix is not a rare occurrence. When the diagnosis is made, the patient should be operated on.

Treatment Immediate surgical intervention is indicated in all cases. Of 36 cases in which the outcome was mentioned 4 terminated fatally and 6 had a stormy course but recovery took place.

Diagnosis of Ectopic Pregnancy by Hysterosalpingography Borge Nielsen *Acta radiol., Stockh* 1947 28 185

Hysterosalpingography is infrequently a diagnostic aid in ectopic pregnancy. A 35 per cent water soluble contrast media is used and films are made in varying projections. The rate of media absorption as well as the manner in which the contrast media fills the pregnant tube are observed by serial films.

Pertinent roentgen findings are

1. Lack of filling of the salpinx and uterine atony
2. Segmental irregularity of the obstructed salpinx
3. Salpinx spasm
4. Nonvisualization of the ovum in the tube.

The author reports the cases of 25 patients on whom hysterosalpingography was done for suspected ectopic pregnancy. Among the first 12 instances the roentgen findings were positive in 11. In the second group of 13 cases it was desired to rule out ectopic pregnancy, and this was done in 12 of them.

The author believes that the danger of miscarriage is not a contraindication to the procedure. However the procedure should not be done indiscriminately. This examination is certainly a worthwhile adjunct to the clinician's diagnostic armamentarium.

MAURICE D. SACHS, M.D.

An Epidemic of Inhalation Lead Poisoning with Characteristic Skeletal Changes in the Children Involved George Cooper Jr *Am J Roentg* 1947 58 219.

The clinical picture of various manifestations of plumbism have been described many times since about 300 B.C. when Hippocrates recorded his findings in a case of lead colic in an extractor of metals. Prompt recognition of plumbism in children is more important than in adults for children react to small amounts of lead and more severely. This is true especially of those under 4 years of age. Epidemics of lead poisoning have been reported in which the source of the lead was traced to the use of storage battery casings for fuel. In Stanton, Virginia there was an epidemic due to this cause. The author discusses the findings in the 19 patients examined. Only 4 patients failed to show abnormal metaphyseal densities on roentgen examination.

The symptomatology in poisoning due to lead inhalation is identical with that due to lead ingestion. The incidence of ingested lead poisoning is highest in spring and summer because the vitamin D producing action of sunlight increases the absorption of ingested lead as well as of calcium. There is no seasonal incidence from inhaled lead. The early symptoms are gastrointestinal—loss of appetite, vomiting, constipation and abdominal cramps. Persistent and

Fig. 1 (Nielsen) A hypermobile uterus which ejected the perabrodil through the fallopian tubes immediately. The pregnant salpinx ends in the shape of a funnel, but it is partly covered with irregular stripes and patches of contrast medium.

Fig. 2 (Nielsen) Same as figure 1 but some time after the injection. The contrast medium is more distinctly visible.

more severe poisoning frequently leads to peripheral neuritis and palsy in adults and occasionally in children. Anemia is a fairly constant finding. Meningo-encephalitis is the most serious development. It is frequent in children. The symptoms are persistent projectile vomiting, changes in the victim's mental state (irritability and lethargy), visual disturbances and alteration of the pulse and respiratory rates. These initial symptoms are followed by delirium, stupor, coma, elevated blood pressure, choked optic discs, convulsions and separation of the cranial sutures.

tures. Corneal and optic atrophy are frequent sequelae.

In children the most valuable diagnostic procedure is roentgenographic examination of the skeleton. The x-ray findings are those of homogeneous metaphysical densities. The zones of increased density vary in width up to about 0.5 cm. and vary in density.

The metaphysical densities are most marked where the bone growth is most active—in the ends of the long bones at the anterior ends of the ribs and in the iliac crest. There are several other conditions which produce zones of increased density in the metaphyses. The diagnosis of lead poisoning cannot be made without confirmation from the history and clinical findings. F. W. L. HUNTER, M.D.

Further Observations on Fracture of the First Rib. D. Rosby Alderson, *Bull. J. Radiol.* 1947 30 345

The author published in November 1914 an article on "Stress Fractures of the First Rib." Various American workers denied the possibility of a spontaneous fracture of the first rib and believed that such an injury could occur only from direct trauma. The author believes that fracture of the first rib does occur frequently from muscular violence; that complete bony union does occur; that nonunion and the formation of a false joint are encountered; that there may be symptoms sufficient to cause the patient's report to his physician; and also that this condition more frequently occurs without sufficient pain to require radiological examination or even to warrant a visit to the doctor.

There is presented a series of case histories of subjects showing the abnormality under review. In one or both first ribs showing evidence of the fracture, sometimes spontaneously, with or without subjective symptoms, sometimes following severe and usually unaccustomed muscular stress, either related to a single episode or more frequently to a particular kind of job, namely, the lifting and carrying of heavy weights.

The radiological evidence has been supported by roentgenocryptoscopia in some cases demonstrating the healing process and in some cases complete bony union occurred. In other cases research into the roentgenograph revealed a bone spur or growth, but no definite fracture. The author believes it is probable that spontaneous fracture of the first rib is more common than congenital abnormality. ALAN D. O. MURPHY, M.D.

The Roentgen Appearance of Primary Reticulum Cell Sarcoma of Bone. Robert S. Sherman and Ruth Evelyn Snyder, *Am. J. Roent.* 1947 5 121

Since then a number of other case reports have appeared in the literature.

The authors observed 17 cases of primary reticulum cell sarcoma of bone, all of which were confirmed histopathologically by at least one biopsy.

The literature contains no reference to the nature of the roentgen studies in reticulum cell sarcoma of bone although often the appearance is highly characteristic. The following factors are of importance:

1. Location in skeletal system. About 75% of the tumors involve the tubular bones of the long bones located in the region of the knee.

2. Location in bone. The tumors may occur in the diaphyseal, metaphyseal or epiphyseal region so that the location in bone has no particular significance.

3. Site of origin. In the vast majority of cases tumors arise from the medullary or cancellous bone.

4. Symmetry in bone. This occurs in 10% of the bones. About one third of the tumors are symmetrical.

5. Direction of growth. In one-half the cases the growth of the tumor is entirely endosteal, in the other half with very few exceptions it is predominantly endosteal.

6. General configuration. An oval configuration occurs most frequently with the following characteristics:

7. Destruction and production in medullary bone. Medullary destruction is a constant feature. Productive changes, i.e., bone formation, calcification, or osteoclastic deposits, are observed in about one-half of the cases but rarely exceed the destructive changes.

8. Structure of the tumor. The structure of the osseous portion is a patchy arrangement of areas of destruction intermingled with similar areas of production. The periosteal portion has no pattern there being no calcification in the soft tissue now apart from the periosteal reaction.

9. Boundary of the tumor. One of the outstanding features of reticulum cell sarcoma of bone is its ill defined boundary so that it is very difficult to determine the precise extent of the tumor.

10. Condition of the cortex. Cortical thickening is a constant finding but no expansion or malformation of the cortex is present.

11. Condition of periosteum. Perfectly normal periosteal reaction is found on cancellous bone but in the thin areas of the cortex the periosteum is often irregular with a moderate periosteal reaction at the margins of the tumor.

12. Periosteal reaction. The majority of the

15 **Multiplicity** There is never involvement of more than one bone.

16 **Rate of growth** The duration of symptoms for an average of 6½ months as well as the roentgen findings of periodical check up examinations suggest that reticulum cell sarcoma is a rather actively growing tumor.

17 **Response to irradiation** The immediate response is very satisfactory. The penosaceous mass disappears first, followed by re-establishment of the cortex, absindence of the periosteal change and finally by reossification of the destroyed area the density being slightly greater than in the normal bone. The late results, likewise are very encouraging. In the authors series 5 patients are well 3 years or more after treatment, 5 patients are well 3 years after treatment 3 died and the remainder were treated more recently.

The differential diagnosis of reticulum cell sarcoma of bone from osteogenic sarcoma of medullary origin is often difficult. The most important distinguishing signs are the radioresistance of the osteogenic sarcoma in contrast to the reticulum cell sarcoma and the lack of reparative changes following roentgen therapy. Other conditions that have to be considered in the differential diagnosis are Ewing's tumor metastatic cancer in bone osteomyelitis tuberculosis, neuroblastoma and lymphoblastoma.

The case histories of all 17 patients are presented and their respective roentgenograms reproduced for the purpose of illustration.

The conclusion is reached that reticulum cell sarcoma of bone is relatively benign and runs a long course with not infrequent 5 year survivals. Irradiation constitutes the sole method of treatment and there is some evidence that it may be a radiocurable tumor.

T. LEUCUTIA, M.D.

Roentgen Diagnosis of Pigmented Villonodular Synovitis and Synovial Sarcoma of the Knee Joint. Raymond W. Lewis. *Radiology* 1947 49 16.

In 1941 Jaffe, Lichtenstein and Sutro grouped under the name of pigmented villonodular synovitis of the knee joint, lesions formerly described in the literature under a wide variety of designations such as chronic hemorrhagic villous synovitis, giant cell fibrohemangioma, fibrohemosideric sarcoma, sarcoma fusigigantocellulare, benign polymorphocellular tumor of the synovial membrane, xanthoma, xanthogranuloma, giant cell tumor and myeloplasmoma. They distinguished between a circumscribed and diffuse form of villonodular synovitis and considered the condition as inflammatory rather than neoplastic.

In the present preliminary report the author deals with the diffuse villonodular synovitis, since the circumscribed lesions are seldom demonstrated roentgenographically. His experience extends to 4 surgically proved cases, which are described in the text, and 7 cases studied only by clinical and roentgenographic means.

The general roentgen characteristics of the diffuse villonodular synovitis and the diffuse intracapsular tumors of the knee joint of which synovial sarcoma (synovioma) is the most common are often identical. They are as follows: bones of a young adult monarticular involvement, excessive amount of synovial tissue which may appear smooth in outline and homogeneous in density or nodular in outline and of varying density, normal joint spacing with no indication of cartilage involvement and complete absence of osteoporosis or atrophy of the leg.

Clinically as a rule there is a long history of swelling of the knee extending from one to several years, no known etiology, relatively little discomfort or disability, no fever and a normal or somewhat increased sedimentation rate.

Although as mentioned above diffuse villonodular synovitis and synovial sarcoma of the knee joint are frequently identical in their roentgen appearance the author found 3 criteria which may permit a differentiation: (1) if the nodular soft tissue masses are in part or wholly outside of the joint capsule, the lesion is not villonodular synovitis, but may be synovial sarcoma, fibrosarcoma or some other condition; (2) if the lobulated soft tissue masses in or near the joint contain scattered or irregular deposits of amorphous lime, the lesion is almost certainly a synovial sarcoma; and (3) if the lesion of the soft tissues of the joint has invaded bone the condition is probably synovial sarcoma.

In the 4 cases described in the text the treatment consisted of one or several synovectomies. However the results were so disappointing that in the more recent cases roentgen therapy is being tried. Some good results from roentgen therapy in villonodular synovitis are described in the literature.

In view of the importance from the point of view of treatment of establishing a differential diagnosis between villonodular synovitis and synovial sarcoma, exploratory operation and biopsy would seem definitely indicated in every case.

The article is illustrated with typical roentgenograms and drawings showing the salient points.

T. LEUCUTIA, M.D.

Panroentgen Therapy from the Clinical, Technical and Biological Point of View (La panroentgenoterapia dal punto di vista biologico, tecnico e clinico). Ardino Ratti. *Radiol. med.*, Milano 1947 32 306.

The author in a lengthy article considered it proper to make an examination of the biological, technical and clinical problems involved in panroentgen therapy (total irradiation of the body with therapeutic roentgen rays) to see how and when much more extended use might be justified. He traces the origin of the idea (submitting the whole body contemporaneously to the therapeutic action of roentgen rays) to the beginnings of the radiological era. Its advancement proposed by Dessauer (1905) and the first clinical applications by Teschendorf (1927), Dale (1928) and Sgalitzer (1932). He believes the term

field for the use of panroentgen therapy is that of the chronic hemopathies especially the not advanced forms. The results in the cases of malignant lympho-granuloma were nearly all negative and in the cases of generalized malignant neoplasms the results were questionable

G ALBIN LIVA, M.D

Irradiation of Experimental Cerebral Tumors. Experimental Production of Brain Tumors in Mice. Katharine Tansley *Radiology* 1947 49 62.

In the first part of this article Tansley deals with the experimental production of brain tumors in mice. After a detailed review of the literature the author describes the method used by herself. Benzpyrene and methylcholanthrene powders have been used. The latter has proved much more successful. 24 sarcomas and 10 gliomas having been obtained in 77 animals. Two strains of mice were used the albino N1 strain, originally obtained from the National Institute for Medical Research London and a mixed pigmented stock of uncertain origin bred in her own laboratory. Because of experimental difficulties only 1 glioma was preserved for transplantation. This now has been successfully transmitted to 103 mice of the N1 strain.

The operation for implanting the carcinogen into the brain tissue was performed when the mice were 2 days old. The glioma used for grafting was obtained from an animal 397 days after the implantation of methylcholanthrene. The operation for the implantation into the brain of the glioma grafts was likewise performed when the mice were 2 days old. Grafts of glioma tissue were successful in every animal that survived the operation. The macroscopic and microscopic appearances of the induced tumors and the grafted gliomas are discussed in detail. Several photomicrographs being used for the purpose of illustration. In general, the grafted gliomas resembled the cerebral tumor described by Lopez in a rat and said by him to be similar to a human glioblastoma isomorphic. The tumor cells invaded the brain particularly through the perivascular and ventricular spaces they also penetrated the true brain tissue without producing any visible reaction or round cell infiltration.

In the second part of the article, Tansley and Wilson give their observations on the effect of roentgen irradiation on the grafted gliomas, 39 of the 85 grafted mice having been subjected to this procedure. The treatment was carried out with 180 kv. (Villard circuit) 0.5 mm. of copper plus 1.0 mm of aluminum which gave a high value layer of 0.95 mm. of copper at a distance of 35 cm and a dose rate of 154 roentgens per minute. The experimental arrangement is described and illustrated with diagrams.

Total doses of from 1 623 to 3,247 roentgens were administered. The effect of irradiation on the growth of the tumor varied greatly. In general, the higher doses were more effective in arresting the growth, but in no case was the tumor entirely destroyed. Five animals died during or within a few hours of the

exposure all showing profuse hemorrhages from the tumor tissue. Other animals were examined from 7 to 18 days after irradiation and were found to exhibit widespread necrosis and diffuse bleeding in the tumor tissue.

The Treatment of Recurrences and Evaluation of Criteria for the Selection of Treatment of Cancer of the Larynx. John V Blady *Am J Roentg.* 1947 58 331

There are three well established methods for the treatment of cancer of the larynx laryngofissure laryngectomy and irradiation.

The purpose of the present study is to review the recurrences that developed at the Temple Univer-

Criterion	Recommended Treatment
Metastases Cervical metastases present	Irradiation 1. primary lesion Irradiation and/or surgery and/or radio
b. Cervical metastases absent	Laryngofissure 1. Laryngectomy 2. Irradiation
Histopathology a. Squamous cell carcinoma, Grade 1 and 2	Laryngofissure Laryngectomy 3. Irradiation
b. Squamous cell carcinoma, Grade 3	1. Laryngofissure Laryngectomy
c. Squamous cell carcinoma, Grade 4	Irradiation In early cases limited to 30 ph. 30. Laryngofissure may be indicated
Extent of Involvement a. Growth limited to one cord, not involving arytenoid or posterior commissure	Laryngofissure
b. Growth limited to anterior commissure and anterior third of each cord	Laryngofissure 1. Irradiation
Growth involving one cord, ventricle	Laryngofissure
d. Subglottic extension	Laryngectomy
Growth involving anterior commissure, cord and base of epiglottis	Laryngectomy
f. Growth involving cord, ary-epiglottic fold with limitation of mobility	Irradiation 2. Laryngectomy
a. Growth involving posterior commissure, pyriform fossa, aryepiglottic fold and epiglottis, or partly well	Irradiation
Mobility and Stability Impaired mobility of cord	Irradiation Laryngectomy
b. Partial impairment of mobility of larynx	Laryngectomy Irradiation
c. One side of larynx fixed or greatly impaired	Laryngectomy
General Factors a. Presence of other disease contraindicating radical surgery	1. Irradiation Laryngofissure
b. Temperament of patient—If patient cannot become adjusted to laryngectomy	Irradiation

higher as well as earlier incidence in mice following doses as low as 11 roentgens per day when compared to the controls.

Histological studies as well as breeding experiments showed that radiation injury to the ovary of the mouse is irreversible and cumulative. Radiation injury to the testes of mice and guinea pigs on the other hand is reversible and cumulative only to a certain degree. No conclusive evidence for the production of genetic changes was obtained in studies on mice exposed continuously up to six generations to 1 roentgens per day after fertilization of the ova took place.

The following conclusions were drawn by the authors from their experimental results. The blood picture is of little value in determining radiation damage except in the case of obvious overexposure. The carcinogenic action and sterility effects dominate the picture of radiation injury. The present permissible dose of 1 roentgen per day in the human should be maintained. Due to the considerably higher as well as earlier incidence of ovarian tumors in mice following cumulative doses of 11 roentgens per day when compared to that in the controls the permissible dose should be reduced for women to perhaps 0.2 roentgens per day or their time of exposure should be reduced to a few years. Since there was no evident radiation injury to the skin of experimental animals exposed to 8.8 roentgens given in 8 hours per day to a total dose up to 10,000 roentgens a permissible dose to the hands of 1 roentgen per day might be considered safe if the rest of the body does not receive more than 1 roentgen per day.

J H FRIED M D

The Hematological Effects of Ionizing Radiations in the Tolerance Range. Leon O Jacobson and E. K. Marks. *Radiology* 1947 49 286.

The authors report the effect of continued whole body irradiation from gamma rays on the hematopoietic system of mice, rabbits and guinea pigs with daily doses of 8.8 4.4 2.2 1.1 and 0.1 roentgens given in 8 or 24 hours per day for periods as long as 3 years. This work was done in conjunction with controlled studies of the peripheral blood of personnel exposed or potentially exposed to radiation during work performed on the Plutonium Project.

From the results of these studies the authors conclude that a lymphocyte reduction in the peripheral blood is the most sensitive indicator of acute or subacute exposure to externally originating ionizing radiation or internally deposited radioisotopes. No hematological change was detectable in the peripheral blood in mice rabbits or guinea pigs with a daily whole body exposure to 0.1 roentgen gamma radiation extending over 3 years. In some of the timed exposures of 0.1 roentgen per day even though no peripheral blood changes were noted. All three species of animals exposed to doses of 2 4.4, or 8.8 roentgens showed definite hematological changes of

significance after varying lengths of time. The guinea pig is the most sensitive, the mouse intermediate, and the rabbit most resistant so far as hematological changes produced by radiations are concerned.

In studies on the personnel of the Plutonium Project no hematological changes were found which were referable to radiation exposure in the tolerance range. The results of this experimental work however indicate that studies of the hematological constituents of peripheral blood are not reliable for determining possible incipient damage from radiation exposure in the tolerance range, and therefore other clinically applicable tests are urgently needed.

J H FRIED M D

The Tolerance Dose and the Prevention of Injuries Caused by Ionizing Radiations. Rolf M. Sievert. *Brit J Radiol.* 1947 20 306

The risks of radiation injuries have been steadily increasing during the past 25 years because of the use of increasing intensities of x radiation and greater quantities of radioactive substances and because of wider use in such fields as research teaching and engineering where medical knowledge is often lacking and where their administration is in the hands of personnel not familiar with their biological effects. The possible use of atomic energy in the future will further greatly increase the problem of protection against injuries by ionizing radiations and it is probable that it will become a general social problem of prime importance.

In considering protection against radiation interest is concentrated on the effects of the ionizing rays on three parts of the human organism the skin the blood and blood forming tissues and the sex glands and germ cells. The so-called safe tolerance dose is of fundamental importance in all work concerning the prevention of radiation injuries. From previous studies, the safe skin tolerance dose may be fixed at between 0.1 and 0.5 roentgens per day. In determining the blood tolerance dose the term integral dose introduced by Mayneord in 1940 is of importance because it gives a measure of the total energy absorbed by the body. It will be of great value for assessing the risks due to high energy protons and neutrons of which the safe tolerance dose may be much smaller than that recommended for x rays and gamma rays because of their greater biological effect correlating the blood changes with radiation risks in the use of x rays and gamma rays have shown that in all probability radiation quantities as low as from 0.2 to 0.5 roentgens per day can give rise to blood changes after a comparatively short time. The genetic tolerance dose appears to be of the order of magnitude of 100 roentgen per day. Hence, the author believes that a safety tolerance of 10 roentgen per day should not, if possible, be exceeded.

The prevention of injuries caused by ionizing radiation is mainly a question of organization. In Sweden, supervision of establishments using x rays and

Discussion on Radiotherapy in the Treatment of Nonmalignant Superficial Eye Lesions. R. Affleck Greaves, B W Windeyer M Loderman N S Finzi and Others. *Proc R Soc M., Lond.*, 1947 40 570.

R. Affleck Greaves deals solely with the treatment of superficial corneal lesions by means of mild suberythematous radiotherapeutic doses. Eighteen years ago he began treating corneal lesions which occurred in connection with cases of acne rosacea keratitis. Improvement was noted. The eyes whitened infiltrates were replaced by healing scars, and pain and photophobia vanished. He states that radiotherapy does not cure the disease. Exacerbations which are especially prone to occur in spring and early summer can be checked in most cases by means of radiotherapy if this treatment is instituted early. Radiotherapy has proved to be markedly beneficial in recurrent abrasions and superficial punctate keratitis. In these cases the ulceration is usually limited to the corneal epithelial layer and heals without leaving any scar. In some cases attacks may continue in a moderate form after a course of treatment. After a suitable interval treatment may be required. About one half of the patients with superficial punctate keratitis who have been treated have been benefited. Only in obstinate cases of phlyctenular keratitis has it been found necessary to use radiotherapy. In mild cases of spring catarrh when eyelids are normal during the winter months and show fresh manifestations in the early part of each year treatment is indicated. Treatment should be immediate in cases of recurrence. In treatment of other types of corneal ulcer including Mooren's ulcer and deodritic ulcer and any form of deep keratitis radiotherapy has not been successful. B W WINDEYER states that the cardinal principle in radiotherapy of malignant disease of the eye is to avoid or shield the eye itself whenever possible, because of the danger of permanent damage from even moderate dosage. The most common sequelae are those associated with the eyelids and the lacrimal apparatus the conjunctiva, and the lens. Scarring of the lids may cause entropion or ectropion, and closure of the punctum by scar tissue may result in persistent epiphora. Heavy irradiation of the conjunctiva may be followed by chronic conjunctivitis with some loss of sensitivity and chronic irritability. In such cases vascular changes are usually apparent. Microscopically there is degeneration of the arterial vascular endothelium, followed by regenerative hyperplasia with narrowing of the lumen of the vessels, and clinically there is dilatation of the superficial capillaries with permanent telangiectasis. Degeneration of the lens with cataract formation may occur. Typical irradiation cataract is posterior cortical with radiating rows of vacuoles and these may be arrested in the vacuolar stage or may go on to maturity vacuolar opacities gradually becoming scattered through the entire lens cortex, which eventually becomes completely opaque. A mature irradiation cataract shows no special clinical features and re-

sponds as well to operative treatment as do other forms of cataract. The technique used at the Middlesex Hospital has been irradiation of the cornea from the lateral and from the medial sides with a beam which is sharply defined by means of a lead glass applicator with a 2 to 3 cm. diameter aperture. The patient is treated with the eye open and fixated in one position. A dose of 100 roentgens measured at the aperture of the applicator is delivered to each field. The estimated dose received by the cornea is a total between 120 and 130 roentgens per treatment. This dose is repeated at fortnightly intervals up to 4 treatments per series. This treatment may be repeated. The treatment of cases of acne rosacea keratitis gives the most gratifying results. Recurrent erosion and abrasion respond with rapidity but may recur. Superficial punctate keratitis of the multiple erosion type has shown satisfactory response in one-half of the cases. The results of treating spring catarrh have been disappointing.

M LUDERMAN states that radiotherapy has not yet received the recognition it merits by ophthalmologists. The reasons for this are twofold (1) current misconceptions concerning the susceptibility of the eye to radiation damage and (2) the eye diseases for which radiotherapy is suitable are not common hence its field of usefulness is rather restricted. The view that the eye is readily damaged by radiation cannot now be supported as it is largely based on early unsatisfactory experimental work and the ocular disasters encountered by pioneer radiotherapists. Damage to the eye is avoidable in the treatment of nonmalignant lesions but the risk of ocular damage has to be accepted in the treatment of malignant neoplasms which affect the eye or its neighboring structures. Radiation with beta and gamma rays and x rays can be used, each have their own indications. Hemangioma keloids, solitary papillomas, and hyperkeratosis are benefited by radiation therapy. For inflammatory lesions it is less satisfactory and should not be used without additional consideration. In superficial punctate keratitis and rosacea keratitis x ray radiation is of value. An initial dose between 10 and 15 roentgens is used which is gradually increased to from 40 or 50 roentgens per treatment twice weekly until a total dose from 200 to 350 roentgens has been given. Individualization of the treatment is advisable. Corneal ulceration and recurrent erosion are favorably influenced by radiotherapy. Mooren's ulcer presents a special problem. The results of treatment are variable.

A. J. DURDEN SMITH states that Mooren's ulcers are treated by contact radiation with unscreened radium applicators. As a rule 3 treatments at intervals of 6 weeks are given. The dosage of the radium applicators used is of full strength i.e., 5 mgm per square centimeter and is substantially unscreened—the contact surface consisting of 0.1 mm of monel metal. The most usual sizes are 1.0 and 1.25 cm in diameter. The typical applicator gives 6,000 roentgens on the surface. The treatment time is short. Forty ulcers were treated. Eighteen of these healed

radioactive substances is now required by law and such supervisory work is carried out largely by the Institute of Radio-Physics. Every person wishing to be employed in radiological work is obliged to undergo a periodic medical examination. A 6 week holiday has been established for all x ray workers periodic inspections are made of all establishments using x ray or radioactive substances and recommendations for protection are made and enforced. Such control work is organized in combination with research and teaching.

Propaganda and instruction appear to be the most important measures for preventing radiation injuries according to the author. A careful and satisfactory working technique is clearly the most important protective measure. Such a system of regulatory control seems desirable and will undoubtedly be adopted by other countries with the advent of the new atomic age. J. W. H. FAY D. M.D.

Effects of Total Surface Beta Irradiation. John R. Raper. *Radiology* 94:749-54.

Because of superficial absorption, radiation with beta rays in doses below the acute lethal range results in greater gross and superficial damage than that following irradiation with x rays or gamma rays. The lesions produced are inflammation and swelling of the epidermis, dryness of the skin, and ulceration of the skin.

It was found that the larger the animal the greater the time required. Total surface beta irradiation is an acute lethal action in each species at a characteristic dose, but the main wave of mortality occurs later than that noted following irradiation with x rays. The median lethal dose (LD 50) for each species noted from baby rats at 2,200 r.e.p. (roentgens equal to 1 g.h. usual) to rabbits at 17,000 p.

Studies indicated that beta rays a strictly superficially absorbed radiation, leaving about their lethal action by a total skin volume effect while gamma rays which penetrate all elements of the body more or less uniformly do not.

A series of experiments showed that the greatest mortality was in the first 3 days following sublethal irradiation and within 8 days complete recovery is attained. It was suggested that there is a period of convalescence after which no obvious explanation is found.

Other studies showed no direct effect on the cellular activity of the peripheral blood.

JAMES O. LAFRANCE M.D.

Experiments on the Mechanism of the Biological Action of Fast Neutrons. J. S. Mitchell. *Brit J Radiol* 1947 20:53.

The author has made a quantitative comparison of fast neutrons with mean energy between 4 and 5 m.e.v. from a polonium beryllium source and a radium gamma ray source. The estimation method for lethal effects in a female mouse. The experiment was performed to determine whether the

relevant mechanisms of the biological action of neutrons are identical with or differ from those of gamma radiation and whether the effects of the two radiations are completely additive. Determinations were also made of the relative biological efficiency of the two radiations for unit energy dose with different overall exposure times.

The contributions to the tissue dose from fast neutrons and the accompanying gamma rays were determined by measurement of the dose of the ionization in lead by means of small ionization chambers with walls of graphite and a carbon polystyrene mixture. One roentgen of fast neutrons is defined as the dose which produces the same energy absorption per unit volume of tissue as that produced by 1 roentgen of the usual filtered gamma radiation of radium of mean energy approximately 0.8 m.e.v.

Two series of biological summation experiments were carried out. The first involving 24 individual experiments with a mean overall time of exposure of 24 hours and the second 38 individual experiments with a mean overall exposure time of 48 hours. The "mixed" radiations applied consecutively in the orders were mainly one third dose control and one type of radiation and two-thirds dose of the other and vice versa but 50 per cent of the experiments were also used in the second series.

In both series of experiments statistically significant departures from additivity were found following the deaths in from 0 to 20 days after exposure. The mixed radiations consecutively applied were found to have less lethal effect than comparison of either fast neutrons or gamma radiation alone. This result indicates a difference in the mechanism of the biological action of these two radiations. The author explains this difference in the mechanism of biological action of fast neutron and gamma rays as probably being due to a difference in the mechanism of action on the cells. Proliferating cells are more sensitive to gamma radiation during a short interval in the prophase stage of mitosis. It is likely that on account of the high specific ionization of fast neutrons the proliferating cells exhibit a more uniform sensitivity to neutrons than cells in the "resting" stage and mitosis was therefore of the length of the former the main effect of fast neutrons will be shown by resting cells. With regard to tolerance problem it is believed that the effects of fast neutrons and gamma radiation are comparable, nevertheless, be regarded as a dilution from the present standpoint.

The relative biological efficiency of fast neutrons in terms of the efficiency of the gamma radiation was found in the experiments with a mean exposure time of 48 hours to have the value of 3.0 ± 0.6. This is significantly higher than the value for short exposure times. The author believes that this indicates that the lethal effects of gamma rays on normal mammalian cells are produced in part by chromosome effects.

Discussion on Radiotherapy in the Treatment of Nonmalignant Superficial Eye Lesions. R. Affleck Greaves, B. W. Winder, M. Lederman, N. S. Finzi and Others. *Proc. R. Soc. M., Lond.*, 1947 40 570.

R. Affleck Greaves deals solely with the treatment of superficial corneal lesions by means of mild suberythematous radiotherapeutic doses. Eighteen years ago he began treating corneal lesions which occurred in connection with cases of acne rosacea keratitis. Improvement was noted. The eyes whitened, infiltrates were replaced by healing scars, and pain and photophobia vanished. He states that radiotherapy does not cure the disease. Exacerbations which are especially prone to occur in spring and early summer can be checked in most cases by means of radiotherapy if this treatment is instituted early. Radiotherapy has proved to be markedly beneficial in recurrent abrasions and superficial punctate keratitis. In these cases the ulceration is usually limited to the corneal epithelial layer and heals without leaving any scar. In some cases attacks may continue in a moderate form after a course of treatment. After a suitable interval treatment may be required. About one half of the patients with superficial punctate keratitis who have been treated have been benefited. Only in obstinate cases of phlyctenular keratitis has it been found necessary to use radiotherapy. In mild cases of spring catarrh when eyelids are normal during the winter months and show fresh manifestations in the early part of each year treatment is indicated. Treatment should be immediate in cases of recurrence. In treatment of other types of corneal ulcer including Mooren's ulcer and dendritic ulcer and any form of deep keratitis radiotherapy has not been successful. B. W. WINDER states that the cardinal principle in radiotherapy of malignant disease of the eye is to avoid or shield the eye itself whenever possible, because of the danger of permanent damage from even moderate dosage. The most common sequelae are those associated with the eyelids and the lacrimal apparatus, the conjunctiva and the lens. Scarring of the lids may cause entropion or ectropion and closure of the punctum by scar tissue may result in persistent epiphora. Heavy irradiation of the conjunctiva may be followed by chronic conjunctivitis with some loss of sensitivity and chronic irritability. In such cases vascular changes are usually apparent. Microscopically there is degeneration of the arterial vascular endothelium followed by regenerative hyperplasia with narrowing of the lumen of the vessels and clinically there is dilatation of the superficial capillaries with permanent telangiectasis. Degeneration of the lens with cataract formation may occur. Typical irradiation cataract is posterior cortical with radiating rows of vacuoles and these may be arrested in the vacuolar stage or may go on to mature. Its vacuolar opacities gradually becoming scattered through the entire lens cortex which eventually becomes completely opaque. A mature irradiation cataract shows no special clinical features and re-

sponds as well to operative treatment as do other forms of cataract. The technique used at the Middlesex Hospital has been irradiation of the cornea from the lateral and from the medial sides with a beam which is sharply defined by means of a lead glass applicator with a 2 to 5 cm diameter aperture. The patient is treated with the eye open and fixated in one position. A dose of 100 roentgens measured at the aperture of the applicator is delivered to each field. The estimated dose received by the cornea is a total between 120 and 130 roentgens per treatment. This dose is repeated at fortnightly interval up to 4 treatments per series. This treatment may be repeated. The treatment of cases of acne rosacea keratitis gives the most gratifying results. Recurrent erosion and abrasion respond with rapidity but may recur. Superficial punctate keratitis of the multiple erosion type has shown satisfactory response in one half of the cases. The results of treating spring catarrh have been disappointing.

M. LEDERMAN states that radiotherapy has not yet received the recognition it merits by ophthalmologists. The reasons for this are twofold: (1) current misconceptions concerning the susceptibility of the eye to radiation damage and (2) the eye diseases for which radiotherapy is suitable are not common, hence its field of usefulness is rather restricted. The view that the eye is readily damaged by radiation cannot now be supported as it is largely based on early unscientific experimental work and the ocular disasters encountered by pioneer radiotherapists. Damage to the eye is avoidable in the treatment of nonmalignant lesion but the risk of ocular damage has to be accepted in the treatment of malignant neoplasms which affect the eye or its neighboring structures. Radiation with beta and gamma rays and x rays can be used; each have their own indications. Hemangioma, keloids, solitary papillomas and hyperkeratosis are benefited by radiation therapy. For inflammatory lesions it is less satisfactory and should not be used without additional consideration. In superficial punctate keratitis and rosacea keratitis x ray radiation is of value. An initial dose between 10 and 15 roentgens is used which is gradually increased to from 40 or 50 roentgens per treatment twice weekly until a total dose from 200 to 250 roentgens has been given. Individualization of the treatment is advisable. Corneal ulceration and recurrent erosion are favorably influenced by radiotherapy. Mooren's ulcer presents a special problem. The results of treatment are variable.

A. J. DUKOEN SURIN states that Mooren's ulcers are treated by contact radiation with uncrenelated radium applicators. As a rule 3 treatment at intervals of 6 weeks are given. The dosage of the radium applicators used is of full strength, i.e. 5 mgm per square centimeter and is substantially uncrenelated—the contact surface consisting of 0.5 mm of metal mesh. The most usual sizes are 1.0 and 1.5 cm in diameter. The typical applicator gives 6,000 roentgens in the surface. The treatment time is short. Forty ulcers were treated. Eighteen of these healed

radioactive substances is now required by law and such supervisory work is carried out largely by the Institute of Radio-Physics. Every person wishing to be employed in radiological work is obliged to undergo a periodic medical examination. A 6 week holiday has been established for all x-ray workers. Periodic inspections are made of all establishments using x-ray or radioactive substances, and recommendations for protection are made and enforced. Such control work is organized in combination with research and teaching.

Preparation of instructions appear to be the most important measures for preventing radiation injuries according to the author. A careful and satisfactory working technique is clearly the most important protection measure. Such a system of regulatory control seems desirable and will undoubtedly be adopted in other countries with the consent of the responsible agencies. J. W. H. L. 10 31 D

Effects of Total Surface Beta Irradiation. John R. Raper. *Pathology* 1917 49 34

Because of superficial absorption, irradiation with beta rays in doses below the acute lethal range results in great gross and superficial damage than that following irradiation with x-rays or gamma rays. The lesions produced are inflammation and swelling of the epidermis, dryness of the skin and ulceration of the skin.

It was found that the larger the animal the greater the dose required. Total surface beta irradiation results in an acute lethal action in each species at a characteristic dosage, but the main wave of mortality occurs later than that following irradiation with x-rays. The median lethal dose (LD₅₀) for each species, noted from early rats at 2,200 r.p.m. (röntgen equivalent in physical) to rabbit at 17,000 r.p.m.

Studies indicate that beta rays are strictly superficially absorbed, resulting in bringing about their lethal action by a total mass or volume effect while gamma rays which are less penetrating of the body mass are less uniformly lethal.

A series of experiments showed that the greatest mortality in the first 3 days follows a sublethal dose and with a 3 day complete recovery is followed by this there is a period of complete tolerance with no obvious explanation is found.

Blind studies showed no direct effect on the cellular contents of the peripheral blood.

Experiments on the Mechanism of the Biological Action of Fast Neutrons. J. S. Mitchell. *Proc J Pathol* 1916 20 37

The author has made a quantitative comparison of the relative biological effectiveness between a dose of 100 r.p.m. from a point source and a dose of 100 r.p.m. from a point source and a dose of 100 r.p.m. from a point source. The experiments are performed chiefly in terms of the

relevant mechanisms of the biological action of neutrons are identical with or differ from those of gamma radiation and whether the effects of these radiations are completely additive. Determinations were also made of the relative biological effectiveness of the two radiations for unit energy absorbed with different overall exposure times.

The contributions to the total dose from neutrons and the accompanying gamma rays were determined by measurement of the dose of the ionization in lead by means of small ionization chambers with walls of graphite and a 1:1 of a polyethylene mixture. One roentgen of fast neutrons is defined as the dose which produces the same energy absorption per unit volume of tissue as produced by a roentgen of the usual filtered gamma radiation of radium of mean energy approximately 0.8 mev.

Two series of biological summation experiments were carried out. The first involving 21 rats and experiments with a mean overall time of exposure of 24 hours and the second 38 individual experiments with a mean overall exposure time of 48 hours. The "mixed" radiations applied consecutively in different orders were mainly one third dose of neutrons and one type of radiation and two-thirds dose of the other, and vice versa, but 50 per cent of the rats were also used in the second series.

In both series of experiment statistically significant departures from additivity were found following the death in from 20 to 30 days after irradiation. The "mixed" radiations consecutively applied were found to have less lethal effect than comparison of either fast neutrons or gamma radiation. This result indicates a difference in the mechanism of the biological action of these two radiations. The author explains this difference in the mechanism of biological action of fast neutrons and gamma rays as probably being due to a difference in the action on the cells. Proliferating cells are sensitive to gamma radiation during a short period in the prophase stage of mitosis. It is likely that on account of the high specific ionization of fast neutrons the proliferating cell exhibits a more or less sensitive vitri to neutrons than the resting stage and mitosis so that because of the length of the former the main effect of fast neutrons will be to destroy resting cells. With regard to tolerance problems it is believed that the effect of fast neutrons and gamma rays is additive from the standpoint.

The relative biological effectiveness of fast neutrons in terms of the efficiency of the gamma rays was found in the experiments with a mean exposure time of 48 hours to have the value of 3.0 to 3.6, i.e., a gamma ray is 3 to 4 times more effective than a fast neutron for unit energy absorbed. The author believes that this indicates that the lethal effects of gamma rays on normal mammalian cells are produced in a different mechanism from fast neutrons.

Superficial punctate keratitis of the multiple erosion type has shown satisfactory response in one-half of the cases. The results of treating spring catarrh have been disappointing.

M LEDERMAN states that radiotherapy has not yet received the recognition it merits by ophthalmologists. The reasons for this are twofold (1) current misconceptions concerning the susceptibility of the eye to radiation damage and (2) the eye diseases for which radiotherapy is suitable are not common hence its field of usefulness is rather restricted. The view that the eye is readily damaged by radiation cannot now be supported as it is largely based on early unscientific experimental work, and the ocular disasters encountered by pioneer radiotherapists. Damage to the eye is avoidable in the treatment of nonmalignant lesions, but the risk of ocular damage has to be accepted in the treatment of malignant neoplasms which affect the eye or its neighboring structures. Radiation with beta and gamma rays and x rays can be used, each have their own indications. Hemangioma keloids solitary papillomas and hyperkeratosis are benefited by radiation therapy. For inflammatory lesions it is less satisfactory and should not be used without additional consideration. In superficial punctate keratitis and rosacea keratitis x ray radiation is of value. An initial dose between 10 and 15 roentgens is used, which is gradually increased to from 40 or 50 roentgens per treatment twice weekly until a total dose from 200 to 250 roentgens has been given. Individualization of the treatment is advisable. Corneal ulceration and recurrent erosion are favorably influenced by radiotherapy. Mooren's ulcer presents a special problem. The results of treatment are variable.

A. J. DUDZEN SMITH states that Mooren's ulcers are treated by contact radiation with unscreened radium applicators. As a rule 3 treatments at intervals of 6 weeks are given. The dosage of the radium applicators used is of full strength i.e. 5 mgm per square centimeter and is substantially unscreened—the contact surface consisting of 0.1 mm of monel metal. The most usual sizes are 1.0 and 1.25 cm in diameter. The typical applicator gives 6 000 roentgens on the surface. The treatment time is short. Forty ulcers were treated. Eighteen of these healed.

and presented no recurrence for period of 2 years or more. Seventeen lesions were bilateral on arrival. Of these 7 healed on both sides as a result of treatment. Four healed on one of the sides but not on the other and the remaining 6 failed to heal on either side.

W. S. FRIEDMAN said that it was necessary to point out that gamma radiation would not fall off in anything like the same degree per millimeter of tissue as the beta radiation. In that Durden Smith has stated that he gave 6,000 roentgens of the beta radiation.

THORNE WOLFF said that he had seen half a dozen cases of stenosis of the punctum and canaliculus after radiation.

B. THORNE THORNE asked if radium or x-ray application would bring about relief in a case of dermoid poma of both eyes.

WILDEYER felt confident that the dosage which he had described had been given. He did not think that splitting of the canaliculus would correct scarring of the punctum (Wolff). He thought a dermoid poma would quite unlikely be radioreducible (Thorne Thorne).

M. LEDERMAN in referring to the dosage and the treatment of Mooren's ulcer said that with a consistent dose.

FRANK L. HERRICK

Radium Therapy of Hemangioendothelioma of the Uterine Cervix Harry H. Bowling, Robert L. Fricke and James T. McGowan, *Am J Surg* 1947 57 653

The authors report 4 cases in which a hemangioendothelioma occurred in or on the cervix. Of 4 patients 2 are dead but their death can be attributed directly to the neoplasm of the cervix. Two of the neoplasms occurred in unmarried women. In multiparous women. The youngest patient was 39 years of age the oldest 63. The most prominent symptom was bleeding. In these patients menstruation still occurred there was not a prolongation of the menstrual periods with increase in the amount of blood at the periods. Vaginal discharge was not a prominent symptom even when vaginal vault was filled by the tumor. The tumor seemed very radiosensitive which usually is true of tumors of endothelial origin.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Sequelae of Atomic Bomb Explosion George V. LeRoy *J Am Med Ass.*, 1947 134 1143

Army and Navy medical missions studied the results of the explosions of the atomic bombs in Hiroshima and Nagasaki, Japan. The two most impressive features of the investigation were the tremendous toll of casualties and the syndrome due to large amounts of gamma radiation. One-sixth of the casualties were crushed under buildings or were trapped in burning buildings and died instantly from the direct heat of the bomb. About one-seventh of the casualties showed no injury on the day of the explosion but received sufficient gamma rays to become sick 1 to 5 weeks later. By rough estimate about 85,000 persons in Hiroshima and 50,000 persons in Nagasaki required medical care on the day of bombing. The types of injuries that required treatment resulted from the characteristic products of the bomb which are (1) mechanical energy "blast" (2) heat (3) light, and (4) ionizing radiation. These injuries could be classified as wounds, 70 per cent burns 65 to 85 per cent, and radiation more than 30 per cent.

It was impossible to estimate the amount of radiation that any one person received. However it is certain that the intensity of the gamma rays varied with the distance from the bomb by the law of the inverse square and it is also evident that heavy buildings and underground shelters gave more protection than wooden structures and open space.

Those who received the largest amount of radiation developed fever and diarrhea the next day, purpura in 4 to 7 days and then rapidly failed and died. Autopsy findings were those of purpura hemorrhagica with petechiae, gastrointestinal erosion and disappearance of normal lymphocytes and marrow cells.

Most patients developed symptoms between 7 and 28 days after the bombing and this syndrome consisted of epilation, intractable diarrhea, purpura, fever, leukopenia, and anemia. The complications were those found in agranulocytic angina. The loss of hair was rarely complete and in most patients it began to grow again in 2 or 3 months. Leukopenia was the outstanding laboratory finding and recovery was rare when the total count dropped below 600 per cubic millimeter. It is estimated that the mortality in this group was between 50 and 75 per cent.

The least severe form of this syndrome appeared from 3 to 5 weeks after bombing and consisted of weakness, malaise, diarrhea, and mild inflammation of the mouth and throat. Some patients developed epilation. Anemia was constant and often progressive. There was mild leukopenia and thrombocytopenia. The bone marrow was badly damaged but in

most cases showed some evidence of regeneration within 7 to 10 days after injury. Spermatozoa were absent from the tubules of the testes in the majority of the men who received enough radiation to cause symptoms.

The therapy of patients with radiation injury should be directed to (1) maintain fluid and electrolyte balance (2) control infection (3) combat hemorrhagic tendency and (4) combat anemia.

ROBERT MAYO TENNEY M.D.

Melkersson's Syndrome: A Report of 5 Cases, with Special Reference to the Pathologic Observations. Karsten Kettel. *Arch. Otolaryng.*, Chic. 1947 46 341

Melkersson's syndrome is a characteristic facies morbi comprising the following triad: chronic swelling of the face, peripheral facial palsy, and lingua plicata. As a rule the disease begins in childhood or youth with an attack of peripheral facial palsy which may be bilateral and may show a tendency to relapse. Either simultaneously or later (sometimes not until several years later) a swelling of the face occurs, which is especially localized to the lips. The tongue is distinctly furrowed (lingua plicata). The syndrome is characteristic. In the acute stage the disease has been mistaken for erysipelas; in the chronic stage it has been mistaken for acromegaly. Both clinically and pathologically, anatomically the facial palsy shows a close correspondence to Bell's palsy.

In fresh cases the patient should be observed for about 2 months. If there are no signs of beginning mobility after that period decompression of the facial nerve should be performed in accordance with the Ballance-Ducl method. Moreover the same treatment is indicated if the spontaneous mobility has ceased before complete restitution has been obtained and in case of relapsing palsy.

The author presumes that the vasomotor fibers of the face follow a shorter or longer course in or along the facial nerve. Paralysis of the sympathetic fibers involves both paresis of the vascular supply of the facial nerve, resulting in facial palsy and paresis of the vessels of the face followed by edema.

C. FRED GOERNOWITZ, M.D.

A Plastic Operative Procedure for the Repair of Large Circular and Elliptical Body Surface Defects. Boyan Hadjilastamoff. *Plast Reconstr Surg* 1947 2 362

Large circular or elliptical body surface defects are formed chiefly after the removal of malignant tumors, excision of old atonic wound surfaces, and function-hindering scars. After certain injuries there also occurs extensive circular loss of substance which may require normal skin covering.

In the majority of cases the easily performed Thiersch-Reverdin graft may be done. In other

FIGURE 1 (Continued)

ages, and the red, the white, and the yellow. The new contracture of the closure must be effected with minimal skin.

The closure of the wound which is accomplished at one sitting through a flap has the great advantage of being quick and less painful.

The author describes a procedure for dealing with large circular or elliptical defects in which he utilizes neighboring skin and attributes the repair to it.

Considering the local blood supply to the flaps, the author makes a quadrangular (TAB=a) and a triangular (TAB=b) flap. The incision is required to be at least one (AB) inch from the incision line and more or less parallel to the edge of the defect. The old quarter incision (AB) amount appears to be the radius length of the circular defect. The width of the flap (a) should be at least one half to two thirds of the width of the defect. The flaps are mobilized and pulled over the defect. There still remains three unincised areas which are closed by suturing the adjacent skin edges.

This procedure has been successfully applied to three regions of the body—upper humerus, upper back, and ischial and trochanter regions.

LOUIS T. RYAN, M.D.

The Blood Circulation in Pedicle Flaps. Preliminary Studies on a Photo-Electric Test for Determining Its Efficiency. Beverly Douglas and Glenn A. Millikan. *Plast Reconstr Surg* 1947; 1:345.

The present test, in which the authors employ an apparatus developed during the war for measuring continuously the oxygen saturation of arterial blood in man, represents a method of determining the viability of

flaps of tube flaps. The adequacy of circulation is estimated from the period with which blood enters the flap following the release of a tourniquet. The blood content of the flap is measured photoelectrically by a simple modification of an oximeter ear unit. The present method measures only changes in the total amount of blood in the flap. It cannot distinguish between the efficiency of arterial supply and venous drainage. The rapid return of blood to a previously "milked" flap after releasing the tourniquet indicates a good arterial supply but tells us nothing about a leakage of venous drainage. Decreased blood content following release of the tourniquet indicates inefficient venous drainage.

The oximeter ear unit consists of a U-shaped structure bearing a small incandescent lamp on one leg and a photocell assembly on the other.

For the present experiment the unit has been modified to fit on flaps of different thicknesses without any alteration in blood circulation.

Upon releasing the tourniquet around one end of the previously "milked" flap, while the other is kept on, blood enters the flap and the resultant flush reduces the transmission of light. This change can be followed continuously by the lamp on one side of the flap and the photocell on the other.

A typical test consists of applying tourniquets at each end of the tube. The circulation is cut off by tightening the tourniquet at one end; the flap then presses free of blood. Without allowing a return of circulation, the other tourniquet is tightened and the oximeter adjusted. The pressure of the tourniquet at one end is then quickly removed and readings are taken at 5 second intervals for 2 or 3 minutes.

The oximeter test offers a very rapid method of testing the efficiency of pedicle flaps. Predictions of

successful transfer based on the test have been justifi-
fied in all 8 cases in which it has been applied. Since
flaps may safely be transferred as soon as the ox-
imeter test gives evidence of adequate circulation con-
siderable time may be saved between operations.
Preliminary experiments indicate that the photo-
electric method can also be applied to the study of
metabolic as well as circulatory changes in pedicle
flaps, and in small extremities.

LOUIS T. BRADY, M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Fluid Blood in Doubly Ligated Vascular Segments
as a Result of Thrombolysis (Flussiges Blut
durch Thrombolysen in doppelt unterbundenen Ge-
fäßstücken) M. Zehender *Illust. chir. sci.*
1947 14 162.

Two theories have been advanced to explain the
presence of fluid blood within ligated vascular seg-
ments. According to one theory there is an inhibi-
tion or breakdown of coagulating substances as in
carbon monoxide poisoning and asphyxia. The other
explanation as confirmed by the present experi-
ments is thrombolysis or autolytic fibrinolysis. The
Baumgarten experiment of double ligation of the
parts of such vessels as the vena cava, jugular vein
saphenous vein and common carotid artery was
repeated in rabbits, horses, and sheep the condition
of the stagnant blood between the ligatures being
examined at different intervals with modern coagu-
lation tests. In early specimens (taken after 3 days
a firm gelatinous coagulum was found after 3 days
specimens consisted of fluid blood. This fluid blood
did not coagulate spontaneously nor after the addi-
tion of thrombin. A complete lack of fibrinogen sub-
stances was demonstrated. Addition of hemophilic
blood containing fibrinogen caused instantaneous
coagulation. The number of blood platelets in the
fluid blood was also diminished and in later speci-
mens the blood platelets had disappeared altogether.
It is suggested that the blood platelets and fibrin
fluid blood within doubly ligated vascular segments
must be liquefied autolytically or thrombolysed blood
Analogous conditions were demonstrated clinically
in a case of subdural hematoma containing
fluid blood. An increased fibrinolytic titer was de-
monstrated in the circulating blood of a patient with
hematomas of the soft tissues. It is therefore prob-
able that local autolysis of the coagulum is associated
with a general fibrinolysis of the coagulum of local auto-
lysis or thrombolysis in bland thrombophlebi-
tis of the axillary veins and secondary hemorrhage
monstrated in a similar manner the secondary
hemorrhage in traumatic rupture of the spleen and
the intermittent paralysis of cranial nerves following
basal fracture as being due to autolytic changes in

thrombi and coagula. Liquefaction of subdural he-
matomas occurs in a similar manner.
The increase of fibrinolytic power in the circula-
ting blood following the occurrence of hematomas
might also explain the effect of autogenous and foreign
blood injections on the consolidation of pneumonia
(fibrinous coagulation within the pulmonary alveoli).

EDITH SCHWARTZ MOORE.

EXPERIMENTAL SURGERY

**Vascular Reactions during Experimental Hemor-
rhage** Nervous and Humoral Factors of Post
hemorrhagic Peripheral Vasoconstriction in the
Dog (Sur les réactions vasculaires au cours de l'hé-
morrhagie expérimentale. Les facteurs nerveux et
humoraux de la vasoconstriction périphérique post-
hémorragique chez le chien) Leon Binet and M.
Burstein. *Rev. Méd.* 1947 3 168.

As the result of a new perfusion technique, the
authors have been able to study the tonus of the
peripheral vessels in experimental hemorrhage. The
decrease in the blood mass even in cases in which the
resulting hypotension is very slight, produces an
intense peripheral vasoconstriction. This reaction
is essentially of central origin and conditioned by
the increase in tonus of the vasoconstrictor centers
however during the hemorrhage the blood acquires
vasoconstrictor properties. The vasoconstriction is
discharge of adrenalin. Probably because of a
immediate it is weak in those animals which stand
the bleeding poorly and very marked in the opposite
types. It is suppressed by section of the 4 inhibiting
nerves. The degree of anesthesia of the animal also
plays a part. The vasoconstriction may be absent
after a massive or very sudden hemorrhage. In such
a case partial restitution of the blood mass may allow
The posthemorrhagic vasoconstriction may allow
appear because of exhaustion of the centers or fol-
lowing ischemia. It is easy to depress the tonus of
the vasoconstrictor centers which are stimulated by
hypotension.
Increasing the blood mass acts in the opposite
direction and causes a peripheral vasodilatation.

RICHARD KEMZ, M.D.

Intravenously Administered Gelatin—A Toxicity
Study Milton J. Vander Brook, Stanley C.
Lyter, Boyd E. Graham, Noel E. Pomeroy and
George P. Cartland. *J. Lab. Clin. Med.* 1947 33
1115

A highly purified 5 per cent gelatin solution, pre-
pared especially for intravenous therapy in human
beings was well tolerated by dogs when given re-
peatedly for several weeks in amounts commensurate
with the fluid lost by hemorrhage.
The only morphological pathology which might be
attributable to gelatin in this series of experiments
was the presence or increase of sudanophile droplets
in the Kupfer cells. The significance of such a change
is not known. The function of the Kupfer cells was

apparently not altered. None of the dogs developed infection of the respiratory tract or at the sites of bleeding and infusion.

Only the sedimentation rate was altered by gelatin. This phenomenon is common to all macromolecular substances, and occurs also when plasma protein concentration is elevated. Gelatin does not interfere with the formation of hemoglobin or plasma protein, both of which are partially depleted by hemorrhage when infused weekly for periods as long as 3 months.

Gelatin does not appear to be stored in the liver or kidneys. A major portion is excreted by the kidneys. The fate of the balance is unknown.

SMITH, F. M. & M. H.

Experimental Production of Ulcers in Closed Gastric Pouches in Dogs. F. F. Stein, Jr., M. I. Grossman and A. C. Ivy. *J. Surg.* 66: 32-35, 1932.

The authors attempted to elucidate the role which acid-pepsin plays in ulcer production and to ascertain if continuous exposure of gastric mucosa to normal gastric juice would result in ulcer formation. For this purpose they utilized healthy mongrel dogs weighing from 25 to 35 pounds.

In the first group of 5 dogs a portion of the greater curvature of the stomach comprising one third to one half of the fundus was resected according to the Heidenhain technique, but the resected segment was completely sutured into a closed pouch. A clamp was used for the remaining gastric portion.

In the second group of 8 dogs a two-stage procedure was employed, the first being the construction of the usual Heidenhain pouch. After from 9 to 12 days the dog was reoperated upon and the stomach of the Heidenhain pouch was fully sutured in 2 layers, thus creating a closed gastric pouch.

In the third group of 6 dogs primary closure was established as in Group 1, following which an ulcer region of the middle or inferior end of the pouch was attached to the parietal peritoneum underlying the second left nipple which was used as a point of localization. Twenty-four hours later, a 15 gauge needle was inserted through the abdominal wall into the pouch, a pressure determination was made with a water manometer and gastric juice was collected to relieve pressure and also for titration. Late readings were made every 12 to 24 hours.

All 5 dogs in the first group died in 2 to 3 days of acute ulcer formation with perforation and peritonitis.

Four of the 8 dogs in the second group died of acute ulcers with peritonitis in 3 to 8 days following closure of the stomach. One dog which was sacrificed 20 days after closure of the stomach showed a grade of tenfold pouch without pathologic changes. The remaining 3 dogs died of recurrent ulcers without ulcer.

Four of the 6 dogs in the third group died in 7 to 20 days of acute ulcer of the pouch with perforation and acute peritonitis. The remaining 2 dogs died on 13 and 24 days from extraneous causes without pathologic changes in the pouch. All the animals had a free acid concentration of over 300 mEq per liter but acute ulcer of the pouch with perforation.

In the majority of cases acute ulcers with perforation developed in closed Heidenhain gastric pouches. Clinically conditions approaching those encountered in a closed pouch are found in pyloric stenosis, the increased pressure and increased secretory activity often present in this condition may predispose to extension of perforation of an ulcer.

THE CYTOLOGIC METHOD AS AN AID IN THE DIAGNOSIS OF GASTRIC CARCINOMA

RUTH M. GRAHAM, B.S. HOWARD ULFELDER, M.D. and THOMAS H. GREEN, Jr., M.D.
Boston, Massachusetts

CARCINOMA of the stomach is encountered more frequently than is any other malignant lesion today. Surgical extirpation has been the only effective means of treatment but the disease is so insidious in its onset that extirpation is rarely possible. Pack and Livingston in 1940 made the statement that, at no time in surgical history and at no point in the world have the definitive cures of gastric cancer ever exceeded 5 per cent of the total number of cases with this disease. In 1942 Walters, Gray, and Priestley reported 6.2 per cent 5 year cures in a series of 10,890 cases. Abrahamson and Hinton in a recent paper state that only 5 per cent of their 139 cases of gastric cancer could be considered candidates for cure. Welch and Allen at the Massachusetts General Hospital have found 6.5 per cent of 375 patients surviving at the end of 5 years. It is obvious that although gastric surgery has grown steadily more radical and less hazardous the rate of cure remains low.

Cancer of the stomach is usually moderately advanced before it produces any symptoms at all. If any significant increase in the rate of operability with expectation of cure is to be achieved we must devise some means of detecting the disease in its presymptomatic state. One such effort was reported in 1944 by

St. John Swenson and Harvey. Using a technique of rapid fluoroscopic scanning of the stomach, they discovered three malignant gastric tumors in 2,413 individuals over the age of 50 years. None had digestive symptoms of clinical note. Five other patients were explored and benign ulcers were found.

We are presenting in this paper a preliminary report on our experience with another diagnostic measure which may be of value in discovering early gastric carcinoma—cytologic examination of gastric fluid for the presence of malignant cells.

The cytologic method in the diagnosis of carcinoma was introduced by Papanicolaou in 1928 (7). The method depends on the observation that most malignant growths desquamate cells which can be identified after suitable fixation and staining. The original report dealt with uterine carcinoma and has been confirmed by many investigators (2, 5). It was an obvious step to apply the cytologic method to other body fluids. In 1937 Dudgeon and Wrigley reported 66 per cent accuracy in the diagnosis of cancer of the lung by examination of the sputum. Wandall in a series of 100 pulmonary carcinomas found malignant cells in the sputum of 86 per cent. Papanicolaou in 1945 (9) mentions 9 patients in whom the gastric secretions obtained by aspiration were studied. Two had gastric carcinoma and malignant cells were seen in the gastric fluid.

From the Vincent Memorial Hospital Laboratory of the Massachusetts General Hospital, Boston, Massachusetts.

In the past year at the Vincent Memorial Laboratory gastric aspirations from 50 patients suspected of cancer of the stomach were studied by the cytologic technique.

METHOD

1. A fasting specimen of gastric secretion is obtained by a siphon. In this series gastric aspirations were used rather than gastric washings. It is of the utmost importance that the specimen be sent to the laboratory immediately since if there is more than half an hour's delay the cells are digested and no distinct cellular characteristics can be identified.

2. The specimen is centrifuged immediately, the sediment spread on a glass slide and placed at once in a fixative of equal parts ethyl ether and 95 per cent alcohol.

3. After fixation for at least 15 minutes the slides are stained by Japanese method (8).

CYTOLOGY OF GASTRIC SECRETION

Normal cells. Most of the cells normally encountered in the gastric secretion originate in the squamous mucous membrane of the upper gastrointestinal and pulmonary tract. These are large epithelial cells with a clear cytoplasm and a small vesicular nucleus. Often epithelial cells from the gastric mucosa are seen. These appear as cuboidal or columnar cells with an eccentric nucleus which is small and vesicular. Occasionally these columnar cells are flattened and then they appear as great sheets of cells with nuclei of even size and single nucleoli. If the cells are well preserved cellular borders are distinct. If the cell group has undergone some degeneration the cytoplasmic outline may disappear although the nuclei remain sharply defined.

Erythrocytes, neutrophils, lymphocytes and histiocytes are usually seen. Bacteria are common and cocci in groups of four are noted fairly frequently.

Malignant cells. The malignant cells seen in gastric secretion often appear in groups. They have nuclei which are hyperchromatic and usually contain prominent nucleoli. There are no sharp cellular borders. Often the cytoplasm shows vacuolization, a characteristic of adenocarcinoma. There are occasional single

cells which can be identified as malignant. They have large hyperchromatic nuclei and an inadequate amount of cytoplasm.

RESULTS

In this series of 50 cases 24 had carcinoma of the stomach. Cancer cells were seen in the gastric fluid of 15. The error in the positive cases is 37.5 per cent.

All 24 of these patients were explored. Seven of the lesions were resectable and 5 of these had previously shown malignant cells in the gastric secretion. One of the two failures in this small group was a scirrhous carcinoma of the wall of the stomach without ulceration of the mucosa. Such a tumor could not be expected to shed cells into the gastric lumen.

In 26 cases no evidence of cancer was shown. Fourteen patients were explored. Twelve were proved to have benign gastric ulcers, 1 had a neurofibroma of the stomach and 1 a benign duodenal ulcer. The gastric cytology was correctly diagnosed as negative in 25 instances. One positive cytological report was rendered in a case later proved to have a benign gastric ulcer. The error in the benign cases is 3.8 per cent.

Below are abstracted two cases which illustrate the value of the method.

PR. MCH. No. 521265. This 50-year-old man entered the hospital with the complaint of cramping postprandial mid-epigastric pain of 14 months duration. He had obtained relief for the first 3 months on liberal low fat bland diet and antacid medication. The symptoms had then recurred. He had lost 5 pounds in weight over the course of a year but had noted no blood in his stools. Gastric analysis showed 0 free acid in the fasting specimen, there were 27.0 units in the first sample after histamine. Gastrointestinal x-ray examination showed marked spasm of the antrum, probably due to a benign ulcer in the middle third of the lesser curvature. Cytologic examination of the gastric fluid was positive. A subtotal gastrectomy was performed. Pathological examination of the specimen showed a gastric ulcer with multiple foci of carcinoma in situ. Further section revealed one area of invasive growth with penetration beneath the muscularis mucosa and involvement of nerve and nerve sheath. The lymph nodes were negative.

H.S. MCH. No. 521291. This 67-year-old man entered the hospital with the complaint of intermittent severe upper abdominal and substernal pain occurring 1 to 2 hours after eating. He had not vomited and had noted no blood in his stools. He had

lost 20 pounds in weight. *Gastrointestinal x-ray examination* showed an ulcerative lesion (2.5 by 1.5 cm.) in the upper stomach which could be either malignant or benign. *Cytologic examination of the gastric fluid* was positive. A transthoracic total gastrectomy was performed. *Pathological examination* of the specimen showed a benign gastric ulcer. The lymph nodes were negative. These sections were reviewed and one area of preinvasive carcinoma was found at the periphery of the ulcer.

DISCUSSION

Any approach which promises to bring cancer of the stomach to operation sooner than in the past merits attention. Mass radiography is one avenue of attack. We feel that the cytologic method may also be of great value in this problem. Although 9 of the 24 cases of carcinoma in this series were erroneously called negative on cytologic examination only 2 of the 7 resectable cases were missed and 2 extremely early cases were both diagnosed correctly. The observation that preinvasive carcinoma sheds cells which can be recognized as malignant is of fundamental significance. This fact has already been noted in carcinoma of the cervix (4). The increased accuracy of the cytologic method in early lesions may be due to the presence of active healthy malignant cells on the surface of such lesions. In the advanced tumor with ulceration and necrosis only occasional recognizable cells may be desquamated. Since our primary endeavor is to seek out the earlier cases these facts emphasize the value of the cytologic method.

SUMMARY

1. The cytologic method of diagnosis has been applied to gastric aspiration in 50 patients with gastric symptoms.

2. A description is presented of the normal and malignant cells which are noted in gastric fluid.

3. Of 24 patients proved to have carcinoma of the stomach smears were positive in 15 instances.

4. Of 7 patients with resectable lesions of the stomach smears proved to be positive in 5 cases.

5. Of 26 patients without cancer the smear was reported positive in 1 a man with a benign gastric ulcer.

6. Two patients had extremely early malignant lesions. In both the lesions were detected by the cytologic technique.

THE SYNDROME OF OVARIAN PAIN AND INSUFFICIENCY

The Importance of Conserving Ovarian Tissue

GEORGE P. HECKEL, M.D., Rochester, New York

UNLESS it occurs regularly at the time of ovulation ovarian pain is likely to be overlooked or misdiagnosed. Thus cyclic ovarian pain or *Mittelschmerz* described long ago by German gynecologists and more recently believed to be associated with ovulation has been generally recognized but the irregular pain of ovarian origin in the absence of demonstrable pelvic disease has not been considered. It is the purpose of this paper to show by the review of carefully observed cases an association of ovarian pain with ovarian dysfunction and to indicate partly by analogy with known reactions of the ovary in animals the possible mechanism of the ovarian failure.

Obviously if there is any possibility of an association of ovarian pain and ovarian insufficiency ovarian tissue should be conserved. It would seem redundant to say that ovarian tissue should be saved for no one would hold that any tissue should be removed unless it is abnormal or useless and potentially abnormal. But the protean nature of the ovary makes it subject to mutilation and removal by those unfamiliar with ovarian physiology and pathology. Graafian follicles and corpora lutea varying greatly in size are all too frequently mistaken for cysts and innocuous cysts of the follicle or corpus luteum resulting perhaps from a temporary upset in the endocrine mechanism lead to the removal of the entire ovary. Many women suffer no ill effects from unilateral castration but there are others in whom there appear signs of ovarian failure. If pain to the ovary because of which perhaps the ovary was removed was associated with ovarian insufficiency in the intact woman loss of half of her already inadequate ovarian tissue will make matters

worse. Pain may develop in the remaining ovary and such symptoms of ovarian insufficiency as she may have had are sure to be aggravated. The inadvisability because it is unnecessary of removing small ovarian cysts has been pointed out (13) and the dangers of this procedure have been noted (9). The possible implications of the removal of ovarian tissue can be realized only when one considers the known reactions of the ovary in animals to experimentally induced ovarian insufficiency.

It is known that in animals which have had one ovary removed the remaining ovary increases in size and sheds a greater number of ova. Beyond a certain point however removal of ovarian tissue results in disturbed ovarian function. If much more than half of the ovarian tissue is removed, that is one ovary and part of the second, failure of ovulation and cystic changes result (to 11). A certain mass of ovarian tissue probably varying in different individuals must be present in order for it to hypertrophy adequately and restore the disturbed endocrine balance.

It is apparent that in the woman removal of one ovary results in the increased activity of the remaining one for the menstrual cycle is not usually altered by the operation. The remaining ovary almost immediately does the work formerly accomplished by two. It is not so apparent however and not generally recognized by clinicians that the remaining ovary increases in size while performing the added function. It is also not realized by many who remove ovarian tissue that there is a limit to the amount that can be removed beyond which seriously disturbed function associated with cystic changes occurs. The following case is illustrative.

ILLUSTRATIVE CASE. When this 25 year old woman was first seen she complained chiefly of persistent vaginal spotting for the past 20 days. Menstruation, regular until the present episode had begun at the age of 15.

From the Department of Obstetrics and Gynecology, The University of Rochester School of Medicine and Dentistry. Presentation of part of this material was awarded the Palmer Drug Company Prize of the Rochester Academy of Medicine in 1944.

She had been married 3 years, there were no pregnancies.

Two years previously she had a right salpingo-oophorectomy because of pain in the right lower quadrant of the abdomen. Two years before that she had had an appendectomy because of similar pain. Four months before she was first seen her left ovary had been resected.

Physical findings were negative. During the next 2 weeks, the patient began to experience hot flashes. The spotting which increased gradually in amount stopped after a total duration of 38 days. Spotting recurred 10 days later and it was followed in 2 weeks by a profuse menstruation.

The diagnosis and findings at the first operation when the right ovary was removed could not be learned, but examination of the hospital record covering the second operation 4 months previously when part of the remaining ovary was removed revealed that the operation was done because of a supposed mass on the right side which proved to be caused by postoperative adhesions. The left ovary was described as 3 to 4 times the normal size. Apparently because of this enlargement two-thirds of it were resected. Examination of the slides prepared from the tissue removed revealed entirely normal ovarian tissue including many graafian follicles and a fresh corpus luteum. The loss of ovarian tissue was progressive. With one ovary apparently normal function continued and the ovary increased in size. Unmistakable signs of failure followed further reduction of the ovarian tissue.

This case illustrates for the woman the condition which has been called *extreme partial castration*. In the woman as in animals, ovarian fragments may not be able to assume the function of the original ovarian mass.

The importance of growing follicles for normal ovarian function has been demonstrated in the rabbit. Westman (24) and Westman and Jacobson (25, 26, 27) have shown that an adequate amount of estrogen produced by the growing follicles is necessary for the occurrence of ovulation and formation of the corpus luteum; that the life of the corpus luteum is dependent upon estrogen, and that these effects are independent of the hypophysis indicating a direct effect on the ovary. In Westman's experiments when all but one of the graafian follicles were destroyed, ovulation did not occur in that one even in the presence of a sufficient quantity of gonadotrophic hormone. But when estrogen was added ovulation occurred and a corpus luteum was formed. In view of this action of

estrogen in experimentally induced ovarian insufficiency in the rabbit it would seem reasonable to treat with estrogen ovarian insufficiency in young women with the purpose of improving the function of the ovaries in spite of the widespread opinion that the hormone produced by the ovary itself has no direct effect on it. The ovary is peculiar in that it represents two endocrine glands having their maximum activity at different times. The graafian follicles which produce one hormone, estrogen, are followed in the cycle by the corpus luteum which makes another, progesterone.

Westman's experiments indicate that the corpus luteum is dependent on the production of estrogen by the follicles throughout the cycle. The amount of estrogen given and the timing of the administration would be important in therapy aimed at improvement of ovarian function in the woman for it is known that the hormone given in sufficient amount early enough in the cycle will inhibit ovulation, presumably by suppressing the gonadotrophic activity of the hypophysis (21).
